INVESTIGATION of the distribution of oxidative enzyme activity in the optic nerve of the cat<sup>1,2</sup> has revealed that oligodendrocytes, which are restricted to the post-laminar part of the optic nerve<sup>3,4</sup>, are characterized by reactivity for the enzymes of the citric acid cycle, succinic and malic dehydrogenases. Astrocytes, which are found throughout the optic nerve<sup>3,4</sup>, show much less reactivity for these enzymes. Succinic and malic dehydrogenases are also strongly active in the fibre bundles of the optic nerve within and anterior to the lamina cribrosa: within the lamina the bundles are composed of finely myelinated and unmyelinated nerve fibres, but in the prelaminar part of the optic nerve the fibres are almost all unmyelinated. In contrast, the post-laminar fibre bundles show negligible activity of these enzymes and are composed of myelinated nerve fibres. Nicotinamide-adenine dinucleotide (NAD) and NADP tetrazolium reductases have a mixed pattern of activity: they show up in oligodendrocytes, in astrocytes, and in the laminar and prelaminar nerve fibre bundles.

In the first 2 weeks after birth the optic nerve of the kitten is extremely cellular and its glial cells, revealed by histochemical staining, are of irregularly stellate form.

These undifferentiated glial cells are best referred to as glioblasts<sup>5</sup>. They exhibit strong activity of the reductases and of non-NAD linked  $\alpha$ -glycerophosphate dehydrogenase, but reactivity for succinic and malic dehydrogenases is slight or absent. Reductase activity first appears in cells identified as oligodendrocytes during the third week; in the fourth week they show strong succinic dehydrogenase activity. At corresponding times the same enzymes become demonstrably active in the nerve fibre bundles of the prelaminar part of the optic nerve and within the lamina cribrosa. Later, malic dehydrogenase shows an identical distribution<sup>6</sup>. These findings are consistent with the working hypothesis that oligodendrocytes are involved in the energetic support of myelinated, post-laminar nerve fibres<sup>2</sup>.

Present findings concern the distribution pattern of enzymes of the phosphogluconate oxidative pathway. The activity of glucose-6-phosphate dehydrogenase and of 6-phosphogluconate dehydrogenase has been investigated in the optic nerves of adult cats and of kittens grouped according to age: 6-7 days, 10-12 days, 15-16 days, 23 days, 28-29 days and 38 days. Longitudinal cryostat sections, 15 $\mu$  thick, were cut from the orbital parts of the optic nerves; they were incubated at 37°C for between 20 and 120 min. Incubation media were as follows. The stock solution consisted of 0.05 molar glycyl glycine buffer, 0.01 molar potassium cyanide and 0.01 molar magnesium chloride. To this was added 0.25 mg/ml. of nitro blue tetrazolium, 0.25 g/ml. of polyvinylpyrrolidone, 1.0 mg/ml. of NADP and 2.5 mg/ml. of substrate. The final pH was adjusted to 7.1-7.2. Control incubations were carried out in the absence of co-enzyme.

At each of the developmental stages which we investigated the distribution of glucose-6-phosphate dehydrogenase activity was identical with that of 6-phosphogluconate dehydrogenase. In the adult cat there was evidence of strong enzyme activity in astrocytes throughout the optic nerve and in oligodendrocytes of the post-laminar region. There was no distinguishing enzyme activity in the nerve fibre bundles within the lamina cribrosa and in the prelaminar part of the optic nerve. In the kitten optic nerves of the three earlier stages the hexosemonophosphate dehydrogenase response was confined to the glioblasts: at three later stages it was found in both astrocytes and oligodendrocytes. No differences of reactivity distinguished the post-laminar nerve fibre bundles from those at the head of the optic nerve.

The distribution of the hexosemonophosphate dehydrogenases in the optic nerve of both kitten and cat thus differs significantly from the distribution of enzymes of the citric acid cycle and of the tetrazolium reductases. In contrast with enzymes of the citric acid cycle those of the phosphogluconate oxidative pathway are present in the glioblasts that initially populate the optic nerve; at later stages of development astrocytes and oligodendrocytes seem to be equally reactive, and there is no correlation between the reactivity of oligodendrocytes in the post-laminar part of the nerve and that of the laminar and prelaminar nerve fibre bundles. In this respect the distribution of hexosemonophosphate dehydrogenase differs also from that of tetrazolium reductases. These differences throw further light on the relationship between myelinated axons and oligodendrocytes and the metabolically linked cytophysiological unit which they form. The reciprocal distribution of enzymes of the citric acid cycle suggests a linkage concerned with processes involving rapid production of energy. The fact that the enzymes of the phosphogluconate oxidative pathway are not similarly distributed is not unexpected, for the pathway may be concerned not so much with the production of energy as with synthetic activity in nucleotide metabolism and in the metabolism of fatty acids and steroids<sup>7</sup>.

Evidence that the astrocytes may be the cells which support the myelin sheath within the central nervous system has been presented elsewhere<sup>1,4</sup> and is consistent

with our findings. The presence of glioblasts within the optic nerve of the kitten during the first 2 weeks is associated with centrifugal advance of myelination demonstrable by staining with 'Luxol' fast blue; their hexosemonophosphate dehydrogenase activity is therefore likely to be associated with a need for intense synthesis of lipid at this time. The presence of hexosemonophosphate dehydrogenases in the astrocytes of the optic nerve of the later three stages in the development of the kitten and the adult cat may be significant in view of the fact that glucose-6-phosphate dehydrogenase and 6-phosphogluconate dehydrogenase are demonstrable in the cells in myelinating cultures which support the sheath<sup>8</sup>.

### Inhibition of Lysozyme by N-Acyl-D-glucosamine Derivatives

LYSOZYME (N-acetyl muramyl hydrolase, E.C.3.2.1.17) is one of several proteins of which the three-dimensional structure is known<sup>1</sup>. The detailed mechanisms of the enzyme function and specificity are not completely established, but it is known to hydrolyse the  $\beta$ (1 $\rightarrow$ 4) glycosidic linkages, between N-acetyl-D-muramic acid and N-acetyl-D-glucosamine in the glycoaminopeptide component of the cell walls of *Micrococcus lysodeikticus*<sup>2</sup> and those of chitin<sup>3</sup>. The action of lysozyme is inhibited by N-acetyl-D-glucosamine<sup>4,5</sup> and the crystallographic structure of a lysozyme-N-acetyl-D-glucosamine complex has been described<sup>6</sup>. The activity and structure of lysozyme have been surveyed recently in a discussion organized by the Royal Society<sup>7</sup>.

Our present work has been concerned with the inhibitory power of some N-acyl-D-glucosamine derivatives. We assumed that they would bind at or near the site responsible for enzyme hydrolysis. In this work lysozyme (crystallized three times) from hen's egg white was used and the progress of hydrolysis was followed by the reduction in turbidity at 450 m $\mu$  of cell suspensions of *Micrococcus lysodeikticus* at pH 6.2 (ref. 8).

By preparing the  $\alpha$  and  $\beta$  anomers of N-acetyl-D-glucosamine the inhibitory power of each was investigated separately and it was found that the  $\beta$  anomer was more inhibitory than the  $\alpha$  anomer. The results with a mutarotated solution indicated that the inhibitory power of the two anomers was additive (Table 1). The methyl N-acetyl-D-glucosaminides resembled the N-acetyl-D-glucosamines in their inhibitory power, that is, the  $\beta$  anomer was the stronger inhibitor (Table 1). The ethyl N-acetyl-D-glucosaminides showed a weak but definite inhibition. The N-formyl and N-propionyl-D-glucosamines

Table 1. CONCENTRATION OF INHIBITOR ( $10^{-3}$  MOLAR) GIVING 30 PER CENT INHIBITION AT pH 6.2 AND pH 9.2

Inhibitor	pH 6.2	pH 9.2
N-Acetyl- $\alpha$ -D-glucosamine	15.0	—†
N-Acetyl- $\beta$ -D-glucosamine	4.6	—†
N-Acetyl-D-glucosamine*	12.0	6.6
Methyl N-acetyl- $\alpha$ -D-glucosaminide	42.0	26.0
Methyl N-acetyl- $\beta$ -D-glucosaminide	3.5	0.5
N,N'-Diethyl chitobiose*	0.2	—†

\* Mutarotated solution.

† Not determined.

were tested and found to have no inhibitory power up to a concentration of 0.1 molar. N-Methyl-N-acetyl-D-glucosamine also inhibited, although the inhibitory power was weaker than that of the homologue N-acetyl-D-glucosamine.

There was some correlation between the inhibitory power and the effect on the difference spectrum of lysozyme in the region 250–300 m $\mu$ , which can be associated with a red-shift in the spectrum of tryptophanyl residues in the protein<sup>9</sup>. Thus chitobiose gave the biggest spectral change, followed successively by methyl N-acetyl- $\beta$ -D-glucosaminide and a mutarotated solution of N-acetyl-D-glucosamine corresponding to their relative inhibitory power.

These results can be interpreted on the assumption that the derivatives tested bind at position C in the cleft, so designated by Blake *et al.*<sup>1</sup>. N-Formyl-D-glucosamine is of particular interest, for it showed no inhibition or characteristic difference spectrum with lysozyme. This clearly suggests that the methyl moiety of the acetamido group is involved in hydrophobic interactions with residues 108(try) and 98(ileu) of the protein.

Johnson<sup>10</sup> observed an additional optimum for lysozyme activity at pH 9.2 and we have carried out some experiments at this pH. The results showed that the inhibitory power of the derivatives tested at this pH was enhanced (Table 1). We suggest that at pH 9.2 the  $\epsilon$ -ammonium group of lysine 97 acts as a proton donor to form the glycoside carbonium ion and that the negative charge on the carboxylate group of aspartic acid 101 stabilizes the intermediate carbonium ion in accordance with present views on the mechanism of cleavage<sup>11</sup>.

### Morphine cancels Effect of Magnesium on Hormone-sensitive Uptake of Glucose by Muscle

It has been shown that the acute *in vitro* effects of adrenal hormones on the rate of uptake of glucose by diaphragms of chronically morphinized rats differ markedly from the normal effects<sup>1-3</sup>, and the evidence suggests that the changes induced by morphine which affect hormone sensitivity involve a modification of membrane properties<sup>4</sup>. The possibility that such changes depend, at least in part, on an ability of morphine specifically to interfere with the formation and function of metal ion complexes within membranes encouraged us to investigate the effects of

varying magnesium concentrations in the incubating medium used in our experiments.

The effect of adrenaline on the uptake of glucose by muscle is known to be influenced by magnesium concentration<sup>5</sup> and it has been suggested that hormones act as sequestering agents for ions such as those of magnesium<sup>6</sup>. The activity of thyroxine<sup>7</sup>, hydrocortisone<sup>8</sup> and insulin<sup>9</sup> is known to be affected by magnesium concentration. The formation of chelates of magnesium with adenosine triphosphate (ATP) and catecholamines has recently been discussed in relation to membrane function<sup>10,11</sup>. Magnesium-dependent enzymes, including an ATPase sensitive to sodium and potassium ions<sup>12</sup> and a phosphatidic acid phosphatase<sup>13,14</sup>, have been detected in membranes where they are believed to function in a variety of membrane transport mechanisms.

In preliminary experiments with excised rat diaphragm in Krebs phosphate-saline, modified by Herman and Ramey<sup>5</sup>, we found that omission of magnesium from the medium has no effect, but increasing the content of magnesium markedly increases the rate of uptake of glucose, and a maximum effect was attained with double the normal concentration of magnesium. With diaphragm from chronically morphinized rats, on the other hand, the rate of glucose uptake is not affected by changing the concentration of magnesium, even if it is a fourfold increase. The results are summarized in Table 1. As already established, the mean basic rate of glucose uptake by diaphragms of chronically morphinized rats is not significantly different from that of normal rat diaphragm<sup>4</sup> and it can be stimulated by hormones<sup>2,3</sup>.

Table 1. *In vitro* EFFECTS OF MAGNESIUM CONCENTRATION ON UPTAKE OF GLUCOSE BY DIAPHRAGM OF NORMAL AND CHRONICALLY MORPHINIZED RATS

State and (No.) of rats	Ratio of [Mg] B/A	Uptake of glucose (mg/100 g wet tissue/h) (mean $\pm$ SE)		
		A (Mg, 1.28 mM)	B (Mg, varied)	Difference (B-A)
Normal (5)	0	162 $\pm$ 12	164 $\pm$ 7	+2 $\pm$ 13
CM (8)	0	229 $\pm$ 14	230 $\pm$ 12	+1 $\pm$ 12
Normal (5)	0.5	180 $\pm$ 3	175 $\pm$ 9	-5 $\pm$ 10
Normal (5)	1.5	180 $\pm$ 13	241 $\pm$ 15	+61 $\pm$ 9 ( $P=0.002$ )
Normal (5)	2	190 $\pm$ 4	302 $\pm$ 5	+112 $\pm$ 12 ( $P<0.001$ )
CM (7)	2	216 $\pm$ 8	210 $\pm$ 18	-6 $\pm$ 19
Normal (5)	3	194 $\pm$ 2	294 $\pm$ 7	+100 $\pm$ 5 ( $P<0.001$ )
CM (7)	3	216 $\pm$ 11	225 $\pm$ 11	+9 $\pm$ 14
Normal (5)	4	190 $\pm$ 6	296 $\pm$ 9	+106 $\pm$ 9 ( $P<0.001$ )
CM (6)	4	206 $\pm$ 8	215 $\pm$ 10	+9 $\pm$ 14

Hemi-diaphragms were incubated at pH 7.4 and 37° C for 1 h in 2.0 ml. of oxygenated Krebs-Ringer phosphate containing glucose (0.15 per cent). In each experiment, half the excised diaphragm served as a control (A) for the other half (B), in which the magnesium content of the medium varied from 0 to  $5.1 \times 10^{-3}$  molar. CM, Chronically morphinized rats, which had received daily injections of morphine (30 mg/kg body weight) for 5–6 weeks.

In further experiments, details of which will be published elsewhere, to compare the acute effects of morphine, adrenaline and hydrocortisone at different concentrations of magnesium, we find that a significant effect of either the drug or a hormone on the rate of uptake of glucose by normal diaphragm is obtained only with a normal or near normal concentration of magnesium in the medium. With chronically morphinized diaphragm, on the other hand, the effect of either the drug or a hormone appears to be quite independent of extracellular concentration of magnesium.

These findings encourage the view that morphine induces changes in membrane transport systems that are sensitive to adrenal hormones, and that by virtue of its structural analogies to both catecholamines and steroids it competes or otherwise interferes with the formation and function of metal complexes which are involved in the hormone-sensitive transport systems. We are investigating the mutual effects of morphine and adrenal hormones as sequestering agents in model systems, and comparing magnesium distributions in tissues of normal animals with those in chronically morphinized animals.

### Increase in Apparent Peroxide ("Pro-blue") in Pregnant Mice

EARLIER we showed that an oral contraceptive, acting by inhibition of ovulation, decreases the total apparent peroxide in mice<sup>1</sup>. As a corollary to this observation it seemed worth while enquiring whether pregnancy, which also inhibits ovulation, similarly decreases peroxide.

Albino hairless mice (*hr hr*) were weighed daily, with precautions against alarm, for 3 weeks. After the first week experimentals were mated, the male being left with the female throughout the second week. Controls were unmated. Pregnancy was apparent from the increase in weight during the third week and was confirmed *post mortem*. Twelve control and twelve pregnant mice, initially 13 weeks old, were used for this experiment. Control and pregnant mice were used alternately. In three of the experiments, vaginal lavages were taken from each mouse immediately after it was killed with nitrogen.

The term "apparent organic peroxide", or "peroxide" for short, refers to "pro-blue"<sup>1</sup>, a substance or substances extractable from biological material by *n*-butanol and capable of oxidizing leucobright cresyl blue in the absence of air. The peroxide estimations of whole mice and the precautions against alarm were as previously described<sup>2</sup>. For the peroxide estimations of mouse organs, a modified form of the anoxic box<sup>2</sup> was used.

Because the results of the experiment with intact mice showed a significant increase in total peroxide, separate organs were examined to determine its location. As shown in Table 1, there were significant increases of peroxide in the uterus, the ovarian fat plus ovaries and the mammary tissue. The increase in weight of the uterus plus fetuses in the pregnant mice was about 45 per cent of the total increase in weight. The lowered average weight of the

ovarian fat plus ovaries in the pregnant mice suggests a utilization of ovarian fat during pregnancy, the weight of the ovaries being negligible by comparison. The mammary tissue included the skin in the area of the nipples. As far as possible a similar area of skin was taken from each mouse. The pituitary body and adrenals were also examined. The two organs were taken from the same mice but their peroxide contents were estimated separately.

The total increase of peroxide in the organs so far tested, although statistically significant, accounts for only about 6 per cent of the whole increase. Further work is being done on other organs of pregnant mice.

It is not clear why inhibition of ovulation due to pregnancy increases organic peroxide although that due to an oral contraceptive decreases it. One obvious difference between pregnancy and oral contraception is that of hormone activity. Lipid peroxidation is believed to be associated with fatty acid metabolism<sup>3</sup>, and pituitary activity, which is increased in pregnancy, stimulates fatty acid release.

## MICROBIOLOGY

### Effect of Mixtures of Atabrine and Antibacterial Agents on the Emergence of Resistant Strains of *Mycobacterium tuberculosis*

THERE have been numerous descriptions of the successful use of mixtures of antibiotics and atabrine in preventing the emergence of resistant strains of *Staphylococcus aureus* and *Escherichia coli*<sup>1-4</sup>. When a sensitive strain of these organisms was subcultured in an antibiotic, however, the mixture of antibiotic and atabrine was no longer effective in eliminating resistance.

The emergence of strains resistant to chemotherapeutic agents used in the treatment of tuberculosis has narrowed the usefulness of such agents. It seemed worthwhile to investigate the effect of atabrine in suppressing the emergence of strains of *Mycobacterium tuberculosis* resistant to isonicotinic acid hydrazide (INH), dihydrostreptomycin sulphate (DHSM), and 4-aminosalicylic acid (PAS).

The H37Rv strain of *M. tuberculosis* was used. The strain, maintained on Dorset egg agar slants, was sensitive to INH, DHSM and PAS. Drug resistance was determined after the strain had been grown for 14 days at 37°C in Dubos oleic acid liquid medium. The tests were carried out by sub-inoculating 0.1 ml. of a 10<sup>-2</sup> dilution of a 7 day culture in 9 ml. portions of Dubos medium containing atabrine (10 µg/ml.) and serial two-fold dilutions of INH, DHSM and PAS. Atabrine alone inhibited this strain of *M. tuberculosis* at 25 µg/ml. From the tube containing the highest concentration of the drug which exhibited growth comparable with that of the control tubes, 0.1 ml. was sub-inoculated into 9 ml. of medium containing the same and higher concentrations of the drug.

The results of this experiment are presented in Table 1. Although an increase in tolerance to the mixture of anti-bacteria and atabrine does eventually occur with repeated passages, there is every indication that the extent of this resistance is small compared with that obtained

Table 1. µMOLES OF PEROXIDE IN MOUSE AND ORGANS

		Mean weight	Mean peroxide	Peroxide/g
Whole mouse	Control	26.52 g	7.29	0.27
	Pregnant	29.96 g	13.38	0.45
			<i>P</i> < 0.01	
Uterus	Control	0.16 g	0.10	0.63
	Pregnant	1.73 g	0.26	0.15
			<i>P</i> < 0.01	
Ovarian fat plus ovaries	Control	0.54 g	0.14	0.26
	Pregnant	0.32 g	0.23	0.72
			<i>P</i> = 0.02	
Mammary tissue plus adjacent skin	Control	1.88 g	0.10	0.05
	Pregnant	1.80 g	0.18	0.10
			<i>P</i> = 0.01	
Adrenals	Control	4.97 mg	0.03	6.04
	Pregnant	4.87 mg	0.08	16.36
			<i>P</i> = 0.01	
Pituitary	Control		0.02	
	Pregnant		0.03	
			<i>P</i> = 0.20	

Table 1. PREVENTION OF *Mycobacterium tuberculosis* H37Rv RESISTANCE TO INH, DHSM AND PAS BY TREATMENT WITH ATABRINE (10 µg/ml.)

Drug	Treatment	Minimal inhibitory concentration (µg/ml.)					
		No. of passages					
		1	2	3	4	5	6
INH	With atabrine treatment	0.005	0.01	0.01	0.05	0.05	1.0
	Without atabrine treatment	0.005	5.0	100	100	100	100
DHSM	With atabrine treatment	0.1	0.05	0.5	0.1	0.5	0.1
	Without atabrine treatment	0.1	0.1	5.0	5.0	5.0	5.0
PAS	With atabrine treatment	0.1	0.1	0.5	0.1	0.1	5.0
	Without atabrine treatment	0.1	0.5	0.1	0.5	10	>100

with the systems containing the antibacterial drugs alone. It can be seen that the susceptibility of *M. tuberculosis* H37Rv to INH in the absence of atabrine has decreased by a factor of two thousand in the course of six passages, whereas in the presence of a sublethal concentration of atabrine it has decreased only by a factor of two hundred. Resistance to DHSM and PAS also developed, but more slowly than to INH, and represented an increase in the tolerance of the organism to these drugs by a factor of between fifty and a thousand in the absence of atabrine compared with an increase by a factor of between 0 and 50 in its presence. A comparable elimination of drug resistance was obtained when *Mycobacterium bovis*, strain Vallée, was passed in systems containing the atabrine-drug combinations. The significance of these observations is being investigated *in vivo*.

### Effect of Berberine Sulphate on *Entamoeba histolytica*

BERBERINE, an alkaloid derived from the plant *Berberis aristata* Linn., has been shown to be useful in the treatment of experimental cholera in the infant rabbit model<sup>1</sup>. It compares well with chloramphenicol in the chemotherapy of cholera and severe diarrhoea in humans<sup>2</sup>. Results of the investigations on *Entamoeba histolytica* reported here suggest that berberine and its salts, such as berberine sulphate, may have a place in the chemotherapy of amoebiasis.

The original stock culture of *E. histolytica* provided by Dr N. K. Dutta of Haffkine Institute, Bombay, was grown in Boeck and Drbohlav (B.D.) medium and subsequently maintained in this, in LMS<sup>3</sup> and in Pavlova's media. Testing of the drugs *in vitro* was carried out in monophasic fluid media by the standard test-tube method and/or by a capillary tube method described by Woolfe<sup>4</sup>. A culture of *E. histolytica* grown in LMS medium for 48 h, in the presence of mixed bacterial flora, was used. Aqueous solutions of two samples of berberine sulphate, one supplied by E. Merck, Darmstadt, and the other prepared in our organic chemistry laboratory, were investigated.

'Intestopan Forte' (Sandoz) containing broxyquinoline and brobenzoxaldine was used as a standard for comparison. The results, shown in Tables 1 and 2, indicate that berberine sulphate is amoebicidal at a concentration of 0.5–1 mg/ml. and that it acts rapidly. Separate and independent experiments have shown that the observed amoebicidal action is not the result of bacteriostatic or

bactericidal action affecting the associated microflora. The growth of the latter was affected only in concentrations greater than 5 mg/ml. In the same conditions of testing, 'Intestopan' exhibited an amoebostatic action in concentrations of 0.05–0.10 mg/ml.

The morphological changes in the trophozoites after the addition of berberine sulphate include encystation, degeneration and finally lysis. Although the rate at which these steps followed each other differed from sample to sample, at the end of 12 h of incubation at 37° C, very few intact trophozoites could be observed. Preliminary results indicate that berberine sulphate may also prove to be cysticidal.

Experiments on 3–4 week old golden hamsters (average weight 40 g) (Table 3) confirm the results obtained *in vitro*. A dose of 2 mg/kg, given intramuscularly, and of 3 mg/kg when fed orally, administered in a regimen of 3 doses at 4 h intervals (first dose before infection, second dose at the time of infection and the third dose about 4 h after infection), prevents the development of hepatic amoebiasis. Similar results were obtained in rats infected intraeally with trophozoites of *E. histolytica* in which the control groups of animals developed an intestinal form of amoebiasis, while the group treated with berberine sulphate did not.

Berberine and its derivatives are well tolerated by animals in large doses as evidenced in the case of rabbits which tolerate a dose of up to 100 mg/kg administered

Table 3. EFFECT OF BERBERINE SULPHATE (MERCK) ON HEPATIC AMOEBIASIS IN GOLDEN HAMSTERS

Route of administration	Dose/kg body weight	No. of animals in each group	Deaths	Post-mortem observations 4 days after infection
Intramuscular	2 mg	4	0	Normal liver. No trophozoites
	Control	4	1	Liver abscess and trophozoites (five to ten/field) observed in all the survivors and the dead hamster
Oral	5 mg	4	0	Normal liver
	3 mg	4	0	No trophozoites
	Control	4	0	One out of three showed small liver abscess; rest normal
	Control	4	0	Three out of four showed liver abscess with trophozoites; remaining one with normal liver

Hamsters were infected intrahepatically under ether anaesthesia. The drugs were administered in three doses, the first one about 4 h before infection, the second one at the time of infection and the third one about 4 h after infection. The controls received a placebo which was either Locke or Ringer solution. All the survivors were killed after 4 days. Infected livers were examined both macroscopically and microscopically.

subcutaneously<sup>1</sup>. Because of its lack of toxicity at amebicidal concentrations, berberine sulphate may prove to be a promising drug in the chemotherapy of amebiasis and other dysenteries. Clinical trials to test these and other possibilities of prophylactic chemotherapy in areas of endemic amebiasis are now being carried out.

### Agent of Marek's Disease in Tissue Culture

ATTENTION has recently been drawn to the differences between avian leukosis and Marek's disease (neural lymphomatosis) in the chicken<sup>1</sup>. Avian leukosis is caused by a closely related and well characterized group of RNA viruses, but the nature of the causative agent of Marek's disease is not known<sup>2,3</sup>. The *in vivo* assay of blood and tumour material from chicks infected with both the *HPRS B14* classical strain and the *HPRS 16* strain of acute Marek's disease indicates that under the conditions of the experiments the infective agent was strictly associated with the cells and could not be separated from them<sup>3,4</sup>.

Work at these laboratories has been directed towards the development of a tissue culture system for the detection and assay of the infective agent of Marek's disease. Because of the apparent cell-bound nature of this agent, viable cells from affected chickens were either cultured as monolayers or were used for inoculating cultures of cells from uninfected birds. The experiments have been carried out using the *HPRS 16* acute strain of Marek's disease<sup>5,6</sup>. The most striking effects were noticed in cultures of chicken kidney cells prepared as previously described<sup>7</sup>, except that monolayers were grown in 60 mm plastic Petri dishes which were seeded with  $1.5 \times 10^6$  freshly trypsinized cells. Cultures were incubated at  $38.5^\circ\text{C}$  in a humidified atmosphere of 5 per cent carbon dioxide in air. The same effects were noticed both in uninoculated monolayers prepared from the kidneys of diseased chickens and in normal monolayers after the inoculation of cells from affected birds. A virus-like cytopathic effect (CPE) was observed under these conditions 7–10 days after the inoculation of infected material into the cultures. The changes are regarded as a slowly progressing CPE rather than a transformation. Foci of rounded, highly refractile cells appear in the cell sheet. Each focus extends outwards during a further 7–10 days incubation, in which time the cells either retract or detach from the centre giving rise to a microscopic plaque (Fig. 1).

The incidence of CPE in monolayers treated with various cell inocula and in monolayers prepared from the kidney cells of affected birds is shown in Table 1. Of sixteen inocula derived from chickens infected with Marek's disease, thirteen produced CPE in normal cultures of

chicken kidney. Of eighteen different batches of normal chicken kidney cultures, two showed the spontaneous occurrence of CPE. No more than three microplaques were found on each plate in these cases, and after killing the remainder of the group from which these two birds were taken, histological lesions of Marek's disease were found in the nerves of one of six birds examined.

Affected monolayers fixed with methanol and stained with May-Grünwald-Giemsa show that the rounded cells may be mono-, bi- or multi-nucleate. The cytoplasm of such cells is intensely basophilic while the nuclei may contain pink staining Cowdry type A inclusions. Multi-nucleate cells which have not rounded up may be found associated with plaques. Varying numbers of nuclei within these giant cells show nuclear inclusions (Fig. 2). Cytochemical observations on the nuclear inclusions using methyl green-pyronin, Feulgen and fluorescent coriophosphine staining<sup>8</sup> indicate that they contain DNA. Treatment of monolayers with 0.01 per cent crystalline DNase in phosphate buffer (pH 7.2) containing  $10^{-3}$  magnesium chloride at  $37^\circ\text{C}$  for 30 min removes the nuclear inclusions from affected cells when subsequently stained with the coriophosphine fluorochrome.

The addition of 100  $\mu\text{g}/\text{ml}$ . of 5-iododeoxyuridine to the medium of monolayers at the time of infection prevented the development of microplaques showing that the cytopathic effect of the agent was sensitive to an inhibitor of DNA synthesis.

Infected "	None	4/4

\* Marek's disease was diagnosed histologically in the group of birds from which the 2 positive cultures were prepared.

† The number of indicated inocula inducing CPE in tissue culture over the number tested. Each was inoculated into a different batch of tissue culture. Uninoculated control cultures from each batch were free from CPE.

Fig. 3. Linear relationship between the number of versenized cells from an infected culture plated on normal kidney cells and the number of microplaques counted 6 days later.

Plaques which develop under fluid overlay can be counted microscopically after fixation and staining. An inoculum of  $10^6$  tumour cells was found to give rise to between ten and a hundred foci when counts were made 10–14 days later. Further incubation failed to reveal the development of significant numbers of secondary foci, which suggests that spread through the cell sheet occurs by cell to cell contact. The effect was passaged onto fresh monolayers by using cells from cultures showing a cytopathic effect, but not by using the supernatant free of cells. Cells were removed from Petri dishes by treatment with 0.1 per cent trypsin in versene (EDTA), counted, and inoculated onto fresh cultures in a series of four-fold dilutions. On passage small foci of refractile cells were observed 3–4 days after the inoculation of cells. Microplaques were counted 6 days after inoculation. The relationship between the number of cells plated and the number of microplaques obtained is shown in Fig. 3. The slope obtained by regressing these points is  $-0.95$  and indicates a linear relationship.

The infectivity of cultures showing a CPE and of control cultures was tested by the intra-abdominal inoculation of day old chicks from the Houghton Poultry Research Station line of Rhode Island Reds which are susceptible to Marek's disease<sup>4</sup>. Chicks were killed 3 weeks later, and results assessed by histological examination of nerves and gonads<sup>4</sup>. No infectivity was found in supernatant from affected cultures when cells had been removed by centrifugation, but the inoculation of day old chicks with between  $2 \times 10^4$  and  $2 \times 10^5$  cells from affected cultures produced specific lesions of Marek's disease. The result of one experiment is given in Table 2. In addition to microscopic lesions gross tumours of the gonad were found in some instances at 3 weeks, while the controls remained negative. These findings add support to the view that the agent producing the CPE is the cause of Marek's disease. The effects observed in tissue culture may result, however,

Table 2. INCIDENCE OF HISTOLOGICAL LESIONS OF MAREK'S DISEASE IN CHICKS INOCULATED WITH TISSUE CULTURE CELLS SHOWING CPE

Inoculum*	No. of days in tissue culture	CPE inoculated chicks	Proportion of †

† The number of chicks showing histological lesions of Marek's disease 3 weeks after inoculation with tissue culture cells over the number inoculated.

from a latent infective agent commonly found as a passenger in tissue from cases of Marek's disease. Biggs and Payne<sup>3,4</sup> have shown that the infectivity for chicks of blood from cases of Marek's disease is destroyed by ultrasonic disintegration and homogenization, that is, treatments which disrupt the cells. In the present investigation it was found that ultrasonic disintegration or freezing and

Fig. 4. Section of a cell from an infected tissue culture, showing intranuclear particles resembling herpes virus, and smaller granules measuring approximately  $30 \text{ m}\mu$ . The nuclear membrane is in the upper left corner. ( $\times 80,000$ .)

thawing of the tumour cells before inoculation onto tissue culture monolayers prevented the appearance of CPE.

Infected tissue cultures were examined by thin sectioning techniques of electron microscopy and by negative staining. Cell cultures were fixed in 1.5 per cent glutaraldehyde in phosphate buffer, and then fixed in Palade's osmium tetroxide. Embedding was done in methacrylate with 0.5 per cent uranyl nitrate added as a stain. Negative staining was performed by subjecting the infected tissue culture cells to freezing and thawing, suspending the cells in about 1 ml. of distilled water, and centrifuging the resulting suspension at about 3,000 r.p.m. with a desk centrifuge. The sediment was taken up in a small amount of 2 per cent sodium silicotungstate, and immediately applied to a grid.

Sections of cell cultures showed particles in the nuclei measuring about 100 m $\mu$ , and possessing an internal nucleoid and an external membrane (Fig. 4). These particles were consistent with the appearance of the herpes group of viruses. Smaller particles were also present, however, and those in the nuclei measured about 30 m $\mu$  in diameter and were often hexagonal in shape. These may correspond to the granules present in nuclei of cells infected with herpes virus, as described by Morgan *et al.*<sup>9</sup>. Particles have not yet been observed in the cytoplasm or outside the cells.

The negatively stained preparations showed two types of particle, apparently "hollow" (Fig. 5) and "full" (Fig. 6), and both measured about 100 m $\mu$  in diameter. Although capsomeres could be seen in the particles, their symmetry could not be established from the electron micrographs. The 30 m $\mu$  granules were not found in the negatively stained preparations. The conclusion from the electron microscopy was that a virus of the herpes type was present in the infected tissue cultures.

The present findings show that a cytopathogenic agent for chicken kidney tissue culture can be regularly isolated from the tissues of birds experimentally infected with Marek's disease. The effects in tissue culture are only obtained when intact viable cells are inoculated and, so far, no cell free infective agent has been recovered from these cultures. The CPE appears to spread in monolayers by cell to cell contact rather than by the release of free infectious particles into the supernatant. These findings closely resemble those described for the group B herpes viruses<sup>10</sup>, notably the varicella-zoster virus<sup>11,12</sup>. Electron micrographs of infected cells in this study support the thesis that the CPE is caused by a virus of this group. Herpes virus-like particles have been described in the Burkitt lymphoma of man<sup>13</sup> and in the cells of the Lucké renal carcinoma of the leopard frog, *Rana pipiens*<sup>14,15</sup>, which suggests that some herpes viruses are potentially oncogenic. The isolation of these viruses and the experimental demonstration of their oncogenicity, however, have yet to be achieved. The other

Fig. 5. Negatively stained preparation showing a "hollow" particle. ( $\times 400,000$ .)

Fig. 6. Negatively stained preparation showing a "full" particle. ( $\times 400,000$ .)

viruses which have been isolated from frog tumours have not been shown to reproduce the disease and may only be passenger viruses<sup>16,17</sup>. In this study, cultures of cells showing a herpes virus-like CPE have been shown to be oncogenic when inoculated into chicks, reproducing Marek's disease. While these cultures clearly contain the agent of Marek's disease, the observed CPE could result from a passenger virus commonly found in the tissue of chickens. It is felt, however, that a comparison of the results presented here with those found for the agent of Marek's disease *in vivo*<sup>3,4</sup> suggests that the causal agent is a herpes virus which is not readily separated from cells in an infective form.

We thank Dr Dourmashkin of the Imperial Cancer Research Fund for carrying out the electron microscope studies and for providing the electron micrographs. We thank G. Carrington for technical assistance.

### Effect of Suspending Medium on Heat Resistance of Spores of *Clostridium perfringens*

THE degree of heat resistance of spores of the various strains of *Clostridium perfringens* is a matter of both theoretical and practical importance, particularly because the organism is a potential food poisoning species. Studies carried out in various laboratories, by, among others, Hall *et al.*<sup>1</sup>, have indicated that spores of selected strains, when produced in Ellner's medium<sup>2</sup>, are less heat resistant than those produced in SEC broth. Hall *et al.* stated, "It seems probable that the atypical spores noted so frequently in this medium did not possess the heat resistant

characteristic of those produced in foods by the parent strain".

This communication reports further observations of this phenomenon. A strain of *C. perfringens*, NCTC 8238, which was originally isolated from salted beef and is one of the heat-resistant Hobbs strains, was used throughout. Spores were defined as those cells which survived heating at 75° C for 20 min. Spores were produced in Ellner's medium and in SEC broth.

The heat resistance of a part of the spores was initially determined at 100° C in the respective sporulating media, in 16 x 150 mm screw-cap tubes. The tubes, containing 3 ml. of suspension, were immersed in propylene glycol maintained at 100° C to within a few mm of the top of the cap. Before heating, the tubes containing the spore preparations were kept in ice water.

The remaining organisms were separated from their suspending media by centrifugation, washed, resuspended in physiological saline and the heat resistance of a portion was again ascertained. The remaining organisms were recovered from the saline solution; those originally obtained in SEC broth were suspended in the spent Ellner's medium and those from the Ellner's medium were suspended in the spent SEC broth and the heat resistance of each was determined once more.

In a second series of tests, spores produced in Ellner's medium were used to inoculate Noyes's veal broth<sup>3</sup> and were allowed to germinate and multiply. A sample of this culture was used to inoculate SEC broth. Spores forming in the SEC broth were tested for their heat resistance in this broth.

Eight replications of these experiments were carried out. Table 1 summarizes the results from the first series of experiments. The spores produced and suspended in Ellner's medium are much less heat resistant than those in SEC broth; however, when the same two preparations of spores are suspended in physiological saline, their heat resistances are very similar. Utilizing the two spent sporulating media as suspending media for spores had a very drastic effect on the heat resistance of the spores. Those produced in Ellner's medium, but suspended in SEC broth, were as heat resistant as those spores initially produced in SEC broth, whereas those spores originating in SEC broth were quite heat sensitive in Ellner's medium.

Table 1. HEAT RESISTANCE OF SPORES OF *C. perfringens*, STRAIN NCTC 8238, AT 100° C IN VARIOUS SUSPENDING MEDIA

Medium For sporulation	For suspension during heating	Number of positive samples in eight determinations				
		Min of heating at 100° C ‡				
		10	30	60	90	120
Ellner*	Ellner	8	0	0	0	0
SEC†	SEC	8	8	8	8	8
Ellner	Saline (0.85% NaCl)	8	8	2	1	1
SEC	Saline (0.85% NaCl)	8	8	6	0	0
Ellner	Spent SEC	8	8	8	8	8
SEC	Spent Ellner	6	3	0	0	0

\* 2.8 x 10<sup>8</sup> spores/ml.

† 7.0 x 10<sup>8</sup> spores/ml.

‡ Includes come-up time.

In the second series of experiments when, by passing the spores formed in Ellner's medium through a full cycle of germination in Noyes's veal broth and re-sporulation in SEC broth for a total of eight replications, the numbers of positive samples were 8, 8, 7, 7 and 5 for 10, 30, 60, 90 and 120 min of heating at 100° C, respectively. In this case, the suspending medium during heating was SEC broth. A comparison between the results obtained and those presented in Table 1 for spores produced and suspended in SEC broth again suggests the environmental effect on the measured heat resistance of spores.

There are various possible explanations for the results obtained. For example, the effect of the spent SEC and spent Ellner's medium may be only a reflexion of the varying pH of the media; or it is possible that unequal amounts of nutrients which could support germination remained in the two spent media. On the other hand, the heat sensitivity of the spores when they were suspended

in physiological saline during thermal stress suggests that the behaviour of spores of a given strain of *C. perfringens* is predicated by the effect of suspending medium, rather than by basic changes in heat resistant characteristics of the organism.

This investigation was supported in part by a US Department of Health, Education and Welfare research grant from the Bureau of State Service, Division of Environmental Engineering and Food Protection.

We thank Mr Cyrus Mahnke for his technical assistance.

### Genetic Association of Determinants controlling Resistance to Mercuric Chloride, Production of Penicillinase and Synthesis of Methionine in *Staphylococcus aureus*

It is generally accepted that the genetic determinant governing penicillin resistance in *Staphylococcus aureus* is located on an extra-chromosomal fragment<sup>1,2</sup>. This genetic determinant may exist in two alternative states, either as an extrachromosomal element or integrated into the chromosome<sup>3,4</sup>. Strains of staphylococci which are resistant to penicillin are often found to be resistant to mercuric chloride<sup>5</sup>. In addition, there is a genetic relationship between penicillin resistance and the chromosomal loci which govern the ability to synthesize methionine<sup>6</sup>.

This article describes evidence for the genetic relationship between the complex loci determining synthesis of methionine and the determinants governing resistance to mercuric chloride and penicillin. Data are also presented to show that both of these may exist either integrated into the chromosome or on an extrachromosomal fragment.

The parent strains of *Staphylococcus aureus* were resistant to penicillin (Pase<sup>+</sup>) and mercuric chloride (Hg-r) and were able to synthesize methionine (Met<sup>+</sup>). The strain designated as U9W was lysed by bacteriophages 80 and 81 of the International Typing Series. Strain U71 was lysed by phages 47 and 53. Strains sensitive to penicillin and mercuric chloride were designated Pase-Hg-s. The methionine dependent mutants which we used were isolated from strain U71 and described by Humbert and Baldwin<sup>7</sup>. Group C mutants (MetC-5 and MetC-9) grew when supplied with either methionine, homocysteine or cystathionine.

The Pase-Hg-s mutants were isolated after treatment with acridine orange or at an increased temperature of 44° C. After treatment, master plates were prepared and were replicated onto media containing 1 u of penicillin/ml. Colonies which did not grow on the medium containing penicillin were replicated onto brain heart infusion agar (Difco) containing a 1 : 20,000 concentration of mercuric chloride, and were phage typed to ensure derivation from the parent strain.

Methods used for propagation of bacteriophages and for transductional experiments were the same as those used by Pattee and Baldwin<sup>8</sup>. The transduction mixture was inoculated onto the surface of media containing the following selective agents: 0.15 u/ml. of penicillin G potassium; a 1 : 40,000 concentration of mercuric chloride; synthetic media<sup>9</sup> devoid of methionine. Sodium citrate (0.5 per cent) was also added to the transducing media to prevent further phage adsorption.

When strain U9W was treated with acridine orange or exposed to a temperature of 44° C, seventy penicillin and

mercuric chloride sensitive mutants were obtained. In contrast, only a single *Pase*<sup>+</sup>-*Hg*-s mutant was isolated after treatment of strain *U71*. Loss of a function after treatment with acridine dyes<sup>2,10</sup> and increased temperature<sup>11,12</sup> has been accepted as indirect evidence to distinguish between nuclear and extranuclear genetic structures. The results of this investigation have shown the mechanisms which control resistance to penicillin and mercuric chloride exhibited strain differences as demonstrated by the effect of acridine orange and increased temperature on their loss. Neither mutagenic agent appeared to have any demonstrable effect on strain *U71* in contrast to strain *U9W*. The ready loss of both determinants in strain *U9W* after treatment suggested autonomous replication. Failure of strain *U71* to lose the markers suggested that the markers are integrated or closely associated with the bacterial genome.

Although all mutants tested were found to be competent recipients of the *Pase*<sup>+</sup> and *Hg*-r determinants, no resistant recombinants were recovered when various penicillin and mercuric chloride sensitive mutants were used as donors in transduction. These data further support the suggestion that these mutants are sensitive due to loss of the entire genetic fragment.

Employing sensitive mutants of either strain, 100 per cent co-transduction of both the *Pase*<sup>+</sup> and *Hg*-r determinants was obtained when the initial transductants were selected for penicillin resistance. If, however, transductants resistant to mercuric chloride were selected, 100 per cent co-transduction of the penicillinase determinant did not occur (Table 1). The reasons for this variation are unclear although plasmid dissociation proposed by Novick and Richmond<sup>13</sup> is a possible explanation.

In some transduction crosses, all recombinants were initially selected for their ability to synthesize methionine. When *MetC*-9 was used as the recipient, 21 per cent of the transductants recovered were co-recipients of the methionine marker and either the *Pase*<sup>+</sup> or *Hg*-r determinant. These results were obtained after replication of the original *Met*<sup>+</sup> transductants onto media containing either penicillin or mercuric chloride. As shown in Table 2, about 1 per cent of recombinants simultaneously received all three markers. When *MetC*-5 was employed as the recipient, however, all three markers were simultaneously transduced at a frequency of 13 per cent. These results indicated that the determinant for mercury resistance was closer to the *MetC*-5 region.

*Pase* *Hg*

Fig. 1. Diagrammatic representation of the relation of the penicillinase and mercuric chloride determinants to the chromosomal loci determining synthesis of methionine in *Staphylococcus aureus*.

The association between the mercuric chloride determinant and the *MetC*-5 region was determined by three factor reciprocal crosses. When strain *U71* *MetC*-5 *Hg*-r was used as the donor and *MetC*-9 *Hg*-s was used as the recipient, 7 per cent of the transductants recovered were *Met*<sup>+</sup>*Hg*-r (Table 3). These results were obtained after replication of the original *Met*<sup>+</sup> transductants onto media containing mercuric chloride. In contrast, 46 per cent of the *Met*<sup>+</sup> recombinants were *Hg*-r when *MetC*-9 *Hg*-r was used as the donor and *MetC*-5 *Hg*-s as the recipient.

The results of these crosses indicated that the locus governing mercuric chloride resistance was to the left of the *MetC*-5 region and thus located between *MetC*-5 and *MetC*-9. The location of the *Pase*<sup>+</sup> locus in this strain had previously been shown to be to the left of *MetC*-9<sup>6</sup>. A diagrammatic representation of the relationship between these two resistance determinants and the chromosomal loci determining synthesis of methionine is shown in Fig. 1.

The results of this investigation confirm the work of Novick and Richmond<sup>13</sup> in showing that the determinant governing resistance to mercuric chloride and penicillin may be located on an extrachromosomal fragment in strain *U9W*. In strain *U71*, however, this fragment is closely associated or integrated with the host chromosome near the locus which controls the formation of cystathionine. Such data indicate that in addition to the *Pase*<sup>+</sup> locus, the determinant governing mercuric chloride resistance may be episomal in nature.

### Serological Differences between Apparently Typical Pepper and Tomato Isolates of *Xanthomonas vesicatoria*

This communication describes the use of serological techniques to distinguish apparently typical isolates of *Xanthomonas vesicatoria* (Doidge) Dows, obtained from pepper (*Capsicum frutescens* L.) and tomato (*Lycopersicon esculentum* Mill.). Isolates from pepper and tomato are culturally similar, although only tomato isolates hydrolyze starch<sup>1</sup>. A tomato isolate has been found to utilize mannose whereas two pepper isolates do not<sup>2</sup>. Pepper isolates have been found to be more virulent on pepper than on tomato, and tomato isolates were more virulent

on tomato than on pepper<sup>3,4</sup>; such isolates have been distinguished by means of phages. In another report, however, tomato and pepper isolates were shown to be culturally and pathologically similar and could not be distinguished with phages<sup>5</sup>.

We decided to determine whether serological techniques could be used to identify such isolates. Lyophilized cultures of a pepper isolate (Culture No. 11633) and a tomato isolate (Culture No. 11551) of *Xanthomonas vesicatoria* were obtained from the American Type Culture Collection, Rockville, Maryland, so that the isolates studied would be generally available. On potato-dextrose agar, the pepper isolate was bright yellow and the tomato isolate dull yellow or cream; our previous observations suggest that these colours are typical of pepper and tomato isolates. Also the pepper isolate was more virulent on pepper than on tomato, and the tomato isolate was more virulent on tomato than on pepper. Thus the isolates obtained seemed to be representative of pepper and tomato isolates.

Bacterial suspensions were prepared and frozen until used in preparing and evaluating antisera. Antisera were prepared in rabbits, with two rabbits for each isolate. All antisera had titres of between 1:2,000 and 1:4,000, and were frozen without preservative until tested in immuno-agar diffusion plates at room temperature (20°–35° C). In all comparisons, undiluted antiserum was added to the central well and bacterial antigens from disintegrated cells were added to peripheral wells. Sources of antigens tested included original frozen bacterial suspensions, isolates grown for 2 months on potato-dextrose agar, and isolates maintained for several weeks in their respective initial hosts.

For each isolate, antisera from each of the two rabbits reacted identically, and antigens from bacteria maintained by freezing, by growth on potato-dextrose agar, and by infections of host plants gave similar reactions. Illustrations of results are shown in Fig. 1. Pepper isolate antisera versus homologous antigens produced two prominent bands in 1 day, pepper isolate antisera versus tomato isolate antigens produced no bands in 1 day and two faint bands in 2 days. Tomato isolate

antisera versus pepper isolate antigens produced one band in 1 day, tomato isolate antisera versus homologous antigens produced two bands in 1 day. No additional bands were detected in the above tests during several days of incubation.

Results were consistent and show that these isolates can be distinguished serologically. Reactions between homologous antisera and antigens were the only ones which produced two bands in 1 day. Cultural growth and infection of initial hosts did not alter the results, which suggests that differences are relatively stable. Similarities between antisera from rabbits inoculated with a particular isolate suggest that the differences noted are not a result of variations in animals or techniques.

The reactions of the isolates were not reciprocal and perhaps were largely the result of differences in concentrations of antigens. Bands were broad and very likely included confluent factors. Further studies planned include the absorption and electrophoretic separation of factors.

## CYTOLOGY

### The Nucleolus and Trisomy

EVANS<sup>1</sup> has argued that in the human oocyte attachment of acrocentric chromosomes to a persistent nucleolus during the first metaphase of meiosis may be an important cause of non-disjunction involving these chromosomes. The critical stages of meiosis in oocytes are difficult to examine, but Evans's hypothesis may receive indirect support from examples of the mechanism in mitosis. We have recently observed what appears to be such an example.

Fig. 1 is a photograph of a human lymphocyte in mitotic metaphase in which a G group chromosome is

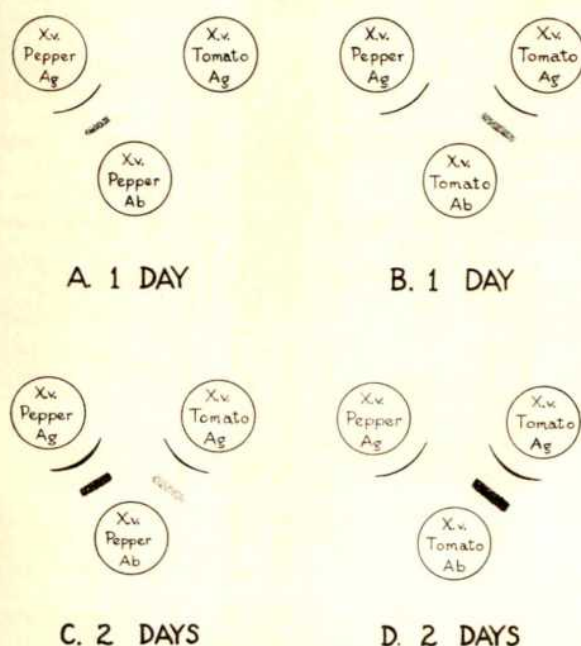

Fig. 1. Band formation after immunodiffusion reactions of *X. vesicatoria* pepper isolate (A, C) and tomato isolate (B, D) antisera with pepper isolate and tomato isolate antigens. Only one band formed between the tomato isolate antisera and pepper isolate antigens, and the production of bands was delayed and faint between the pepper isolate antisera and tomato isolate antigens. Reactions between homologous antisera and antigens always produced two bands in 1 day.

Fig. 1. Metaphase of a human lymphocyte showing a G group chromosome attached to a nucleolus.

detached from the other chromosomes and related by its short arms to a persistent nucleolus.

The preparation was made from a lymphocyte culture stimulated with phytohaemagglutinin and incubated for 72 h. No treatments with colchicine or hypotonic solutions were used. The cells were fixed in a solution consisting of 3 parts methanol and 1 part acetic acid and the chromosomes were spread by an air-drying technique.

The lymphocytes were obtained from a married woman aged 26 who has one son aged 3 and has aborted five times at 8-9 weeks. Cultures treated with colchicine and hypotonic solutions yielded cells of normal karyotype apart from one unusual A.1 chromosome in all the cells examined. This chromosome had an exceptionally obvious secondary constriction which was further from the centromere than usual. The patient denied a history of jaundice or of an illness suggestive of non-icteric hepatitis. Her father gives a history of jaundice and has had several surgical operations on his bile ducts. Her mother, who has had three children but no miscarriages, also had the unusual A.1 chromosome.

### Cellular Distribution of Serum $\alpha$ -Foetoprotein in Organs of the Foetal Rat

THE mammalian foetus synthesizes a serum  $\alpha$ -globulin, called  $\alpha$ -foetoprotein, which is not found in the adult of the species<sup>1-7</sup>. Although interspecies structural differences among the  $\alpha$ -foetoproteins have been noted<sup>4-7</sup>, the protein of each species appears to be a homologue of foetuin, or bovine  $\alpha$ -foetoprotein<sup>5,7</sup>. Synthesis of serum  $\alpha$ -foetoprotein has been shown to occur in the liver in both the rat foetus<sup>8,9</sup> and the human embryo<sup>9</sup>, and in the yolk sac of the rat<sup>9</sup>. The cells responsible for this synthesis are not known, however, and it has been suggested that the haematopoietic tissue of the liver may be the site of synthesis<sup>8</sup>. In the present investigation, the cellular distribution of  $\alpha$ -foetoprotein in organs of the rat foetus was investigated by means of the fluorescent antibody method.

Albino rat foetuses of a Wistar strain were removed from their membranes after gestation for 15-19 days, frozen in tubes immersed in solid carbon dioxide and 95 per cent ethyl alcohol, and sectioned while frozen at 4-8 $\mu$ , either sagittally or in cross-section; the placenta and membranes were similarly frozen and sectioned. The sections were placed on glass slides, thawed and dried, placed in acetone for 10 min and again dried; they were then stained either with rabbit antiserum specific for rat serum  $\alpha$ -foetoprotein (anti-R $\alpha$ ) labelled with fluorescein, or with the same labelled antiserum from which reactive antibodies against  $\alpha$ -foetoprotein had been removed by adsorption with foetal rat serum. The rabbit antiserum had been prepared as described elsewhere<sup>7</sup>; it was labelled with fluorescein isothiocyanate<sup>10</sup> and made specific for rat  $\alpha$ -foetoprotein by adsorption with maternal rat serum<sup>7</sup>. The stained sections were washed in 0.1 molar sodium chloride, mounted in glycerol buffered at pH 8, and examined under the dark field microscope using ultra-violet light from a mercury arc lamp filtered through a Corning '5840' filter as the excitation beam. After selected fields had been photographed, the sections were stained with haematoxylin and eosin and the fields compared with their photographs.

None of the tissues of the rat foetus displayed specific fluorescence after staining with labelled anti-R $\alpha$  except those of the liver and yolk sac (Figs. 1A and C). In the

Fig. 1. A, Section of yolk sac treated with anti-R $\alpha$ , labelled with fluorescein, displaying specific fluorescence in cytoplasm of yolk sac cells. B, Section of yolk sac treated with anti-R $\alpha$ , labelled with fluorescein, adsorbed with foetal rat serum to bind antibodies against  $\alpha$ -foetoprotein; relatively little or no specific fluorescence is apparent. C, Section of foetal rat liver treated with anti-R $\alpha$ , labelled with fluorescein; most of the specific fluorescence is associated with the cytoplasm of parenchymal cells. D, Section of foetal rat liver treated with anti-R $\alpha$ , labelled with fluorescein, adsorbed with foetal rat serum. (All  $\times 150$ .)

liver, the fluorescence was found to be primarily in the cytoplasm of the parenchymal cells (Fig. 1C). Although slight fluorescence of the cytoplasm of some of the haematopoietic cells appeared to be present, the larger portion of the haematopoietic tissue did not show specific fluorescence. In the yolk sac, the fluorescence was associated with the cytoplasm of the yolk sac cells (Fig. 1A). Specific fluorescence was not found in the brain, heart, lungs, thymus, muscle, gastrointestinal tract, pancreas, spleen, kidneys, bone marrow, or placenta. Little or no fluorescence was observed in either the yolk sac (Fig. 1B) or the liver (Fig. 1D), when the fluorescent antiserum was adsorbed with foetal rat serum to bind the antibodies against  $\alpha$ -foetoprotein before staining.

The presence of serum  $\alpha$ -foetoprotein only in the yolk sac and in the liver of the rat foetus as determined in these experiments agrees with the finding that foetal rat liver and yolk sac will synthesize radioactive serum  $\alpha$ -foetoprotein when cultured in the presence of leucine labelled with carbon-14, whereas the other foetal rat tissues will not<sup>9</sup>. The results also suggest that hepatic synthesis of serum  $\alpha$ -foetoprotein probably takes place, primarily at least, in the parenchymal cells.

## Effects of *N*-Methyl-*N*-nitrosourethane on Cells in Tissue Culture

A COMMUNICATION on the morphological conversion of cells *in vitro* by *N*-nitrosomethylurea by Sanders and Burford<sup>1</sup> prompts me to report similar experiments performed about 5 years ago in which the related and very effective carcinogen, *N*-methyl-*N*-nitrosourethane (MNU)<sup>2</sup> was used. Its action *in vitro* was tested on various mammalian cells grown in tissue culture. These included the Syrian hamster fibroblast *BHK* 21/13 *C* cell line<sup>3</sup> made available by Professor M. Stoker, and also fresh cultures of trypsinized baby (or foetal) rat heart fibroblasts. The cultures were maintained in Roux bottles, in Eagle's medium (containing double concentration of amino-acids and vitamins) and Hanks tryptose phosphate broth with 10 per cent calf serum. The cultures were trypsinized and sub-cultured once a week or more often. Explants, 24 h or 48 h old, were used for treatment with MNU of concentrations  $1 \times 10^{-2}$ – $1 \times 10^{-5}$  molar. For this purpose, the medium was removed from the cultures and replaced by MNU dissolved in ethanol (1:10 v/v) and diluted to the desired concentration with phosphate buffer. After 30 or 60 min at 37° C, the MNU solution was decanted, the cultures were washed once with phosphate buffer, and left in fresh medium at 37° C.

Concentrations of MNU of less than  $2 \times 10^{-4}$  molar allowed the cells to survive and to grow. These were collected by trypsinization, centrifuged and suspensions containing  $7$ – $10 \times 10^6$  cells/ml. were injected subcutaneously into homologous animals (0.1–0.2 ml./animal). Control animals were injected with cells grown and collected in a similar way which, however, were not treated with MNU, only with phosphate buffer.

Hamsters injected subcutaneously with *BHK* 21/13 *C* cells treated with MNU developed tumours at the site of injection, which became apparent in a few days, and formed large lumps, about 2 cm in diameter, 1 month after the injection. Hamsters injected with *BHK* 21/13 *C* cells which were not exposed to MNU developed similar tumours, however, though these grew at a somewhat slower rate. In both cases the tumours proved microscopically to be anaplastic sarcomata, which could be transplanted into other hamsters.

In contrast, no tumours were seen in rats which were injected with suspensions of rat fibroblasts, and maintained in tissue culture through only two or three sub-cultures, regardless of whether or not these were treated with MNU. The injected rats were observed for 7 months, during which time no tumours developed and at autopsy no residual surviving tissue was seen at the site of injection.

A single treatment with MNU can have profound effects on cells, which, however, manifest themselves first as inhibition of cell division, and probably correspond to the known "latent period" of carcinogenesis *in vivo*. The inhibitory action of MNU on mitotic division has been observed to last up to several weeks in the case of *Amoeba proteus*<sup>4</sup>; the affected amoebae retained their ability to grow, became greatly enlarged, and when they started dividing, they did so in a most irregular and unpredictable way.

Variations in the size of cells and of their nuclei could be clearly seen in cells of *BHK* 21/13 *C* cultures, when they assumed a rounded up form after trypsinization and were spread on microscopic slides, fixed in neutral formal and stained with, for example, the Feulgen stain. In *BHK* 21/13 *C* cultures treated with MNU the number of enlarged cells were more numerous. The cultures of *BHK* 21/13 *C* cells must have undergone malignant transformation in the course of prolonged subculturing *in vitro*. In some laboratories *BHK* 21/13 *C* cultures are said to contain a virus<sup>5</sup>.

The possibility has to be considered that the malignant transformation of cells in tissue culture occurs in stages<sup>3</sup>, and that MNU accelerates the process. It would be

desirable to establish at which stage this takes place. In the experiments described here, rat fibroblasts that had been subcultured two or three times when they were treated with MNU, and collected a few days later, failed to induce tumours when injected subcutaneously into young rats.

I thank Professor M. Stoker and Dr P. D. Cooper for advice, and Miss Ann McKinnon and Mr I. W. R. Caldwell for technical assistance.

## Time Sequence of DNA Replication in Heteropycnotic X

RESULTS obtained with different techniques suggest that heteropycnotic X, that is, the late-replicating X, in human female cells is not completely inactivated<sup>1-5</sup>. If the chromatin which is not late-replicating can be genetically active, then the observation of bands with little or no labelling by tritiated thymidine in the terminal phase of the *S* period may also indicate the presence of non-inactivated X linked genes on heteropycnotic X. By means of autoradiographic techniques<sup>6</sup>, non-late-replicating regions have been shown on this chromosome, but the validity of this observation is questioned by the finding, in the same experiment, of X chromosomes intensely labelled over their whole length<sup>7</sup>.

Such contradictory findings may simply result from the fact that precursors were available for different times in different cells in the same culture. The greatest difficulty involved in the study of patterns of DNA synthesis in chromosomes results from the necessity to either synchronize or time human cells in culture. Nevertheless, in cultures of asynchronous cells and with tritiated thymidine present in the medium at a constant concentration, it is now possible to arrive at a reasonable approximation of how much of *S* period each cell has spent in contact with the precursor. This is done either by evaluating relative incorporation in a late replicating chromosome<sup>8</sup>, or by using the cumulative curve method<sup>9</sup>. We have attempted to analyse in detail the way in which the synthesis of chromosome X is completed during the final 0.5 h of the *S* period.

Lymphocytes from a healthy woman were stimulated with phytohaemagglutinin by Moorhead's technique<sup>10</sup>. Tritiated thymidine was added to the culture at a final concentration of 1  $\mu$ Ci/ml. 3 h and 45 min before fixation; colcemid at a final concentration of 1  $\mu$ g/ml. was given 1 h and 45 min before fixation. The chromosomes and autoradiographic slides were prepared by the usual methods.

Random examination of 264 mitotic figures showed significant (greater than the background) labelling in sixty-six of these and absence of labelling in 198. The duration of the *G*<sub>2</sub> period was estimated as 3 h and 19 min and the *S* period as 26 min. The labelled cells were arranged in cumulative distribution, by Gilbert's method<sup>9</sup>, to establish the time of contact with precursor in each cell. The cells were then sub-divided into groups of thirteen, equivalent to 5 min of the *S* period, on the basis of a time scale plotted along the abscissa of the curve. All the grains present on the hot chromosome X (the hot-test of group C) of each of these groups were transferred

onto a diagram according to their real position (Fig. 1A). The exact site and intensity of DNA synthesis in each period was obtained by subtracting from each of these diagrams the grains present in the diagram of the period closest to the end of *S* (Fig. 1B).

These data show that the patterns of labelling observed at the end of the *S* period on hot *X* chromosomes are related to the degree of labelling in the cell to which the chromosomes belong and that each pattern pertains to a particular fraction of the terminal period of DNA synthesis. *X* chromosomes of cells which have been in contact with the precursor for about 26 min are almost completely labelled (Fig. 2A). Three non-late-replicating bands appear progressively on *X* chromosomes of the cells of successive periods and these are clearest in the group of cells which have been in *S* for not more than 15 min (Fig. 2B). Of the three bands which emerge from this analysis the widest is at the centromere, and the other two are at the distal extremity of the short arms and between the middle and distal third of the long arms. In the *X* chromosomes of cells that have been in *S* for 5 min or less, the three bands are no longer detectable and labelling is only present at the proximal part of the long arms (Fig. 2C). A more detailed view of how the sequence appears in the various zones of the *X* chromosome is shown in Fig. 1B; in each of the diagrams the number of grains expresses the relative amount of DNA synthesized in the corresponding sub-periods.

Previous investigations<sup>6,7</sup> showed that some *X* chromosomes with zones which are not late labelling are present at the end of the *S* period. Our results indicate that the finding of "cold regions" is an obligatory step in the

Fig. 2. Examples of different labelling patterns of *X* chromosomes belonging to cells which have been in contact with tritiated thymidine (A) for the last 25 min, (B) for the last 15 min, and (C) for the last 5 min of the *S* period.

sequence of the DNA duplication of heteropycnotic *X* and that the synthetic process is completed in those regions at least 25 min before the end of *S*. Thus the presence in the same culture of cells showing different labelling patterns on this chromosome is the consequence of the asynchrony among the cells.

## GENETICS

### Immunochemical Studies on Bisalbuminaemia

BISALBUMINAEMIA is a rare inherited condition, with no clinical features, in which the plasma contains two albumins of different electrophoretic mobilities, usually in equal concentrations: the total concentration of albumin is normal. In all the families so far described, one of the albumins has migrated at the same rate as normal albumin; in some families the second albumin has migrated more slowly and in others more rapidly. Some of the reported variations in the characteristics of the two albumins have been discussed by Tárnoky<sup>1</sup>. The recent finding of homozygotes for the fast variant in two American Indian families has supported the hypothesis that the determinants for the albumins are alleles at a single locus<sup>2,3</sup>.

Earle *et al.*<sup>4</sup> made the first attempt to find an immunological difference between the separated albumins of bisalbuminaemia and normal albumin, using an antiserum to normal serum albumin in immunodiffusion studies. The three albumins showed reactions of identity with each other. Robbins *et al.*<sup>5</sup> suspected an immunological difference when they found that the ends of the albumin precipitin arc were split when immunoelectrophoresis was carried out using large dilutions of whole serum from patients with bisalbuminaemia. No splitting was observed with similar dilutions of normal serum. Split

Fig. 1. Sequence in which labelling bands appear in the five successive sub-periods of the final 26 min of the *S* period. (A) Grains present on the *X* chromosomes of cells labelled between 0 and 5 min, 0 and 10 min, or longer, before the end of *S*. (B) In each sketch the grains actually formed in the corresponding sub-periods.

precipitin arcs can be observed in pure antigen-antibody systems when the antibody is in great excess<sup>6</sup>, however, and this finding alone is not proof of an immunological difference. The reactions of identity observed by Earle *et al.*<sup>4</sup> between the two albumins from patients with bisalbuminaemia and between these albumins and normal albumin, using an antiserum to normal serum albumin, show that the abnormal albumins have lost none of the antigenic determinants of normal albumin.

In a new family with bisalbuminaemia of the slow type, we have tested—we believe for the first time—the possibility that the variant albumin has gained an antigenic determinant as the result of the supposed amino-acid substitution which has altered its electrophoretic mobility<sup>7</sup>. We have shown, by the use of antisera to sera from normals and from patients with bisalbuminaemia, that both the albumins of the affected members of this family are immunologically identical with normal albumin.

The slow albumin of the affected members of the family we tested (Fig. 1) had an electrophoretic mobility relative to the other albumin of 0.90, both on paper and on cellulose acetate membrane in 0.07 molar barbitone buffer, pH 8.6. Potent antisera to sera from patients with bisalbuminaemia were raised in rabbits by the repeated intramuscular injection of sera emulsified in Freund's complete adjuvant. Pure samples of the two albumins were prepared in the following way. A little bromphenol blue was added to a serum, and electrophoresis was carried out in a horizontal starch block using 0.07 molar barbitone buffer, pH 8.6. The albumins appeared to bind bromphenol blue equally, and separated clearly. The bands were eluted from the starch and the albumin-dye solutions in buffer were separately applied to columns of 'Sephadex G-25' equilibrated with water. The albumins were eluted with water, appearing in the void volume of the columns free from dye and from buffer. Each albumin was shown by cellulose acetate electrophoresis to be electrophoretically homogeneous.

Immuno-electrophoresis of whole sera from patients with bisalbuminaemia showed in each case an albumin precipitin arc in the shape of a Cupid's bow, with no evidence of spur formation (Fig. 2). Both antisera were diffused in Ouchterlony plates against the two separated albumins and against pooled normal human serum albumin, each at a variety of dilutions. Reactions of identity were obtained between all the albumins, with no evidence of spur formation.

We conclude that the slow albumin and the normally migrating albumin from the affected members of this new family with bisalbuminaemia have lost none of the

Fig. 2. Immuno-electrophoresis of a 1:5 dilution of serum from a patient with bisalbuminaemia against its own antiserum, showing the precipitin arc of the albumins.

antigenic determinants of normal serum albumin, and have gained no new determinants.

We thank Dr Mary E. Cawley and Dr C. M. Dunn of Saltburn, Yorkshire, who provided details of the family and collected the blood samples.

### Fundamental Theorem of Natural Selection

Li<sup>1</sup> has pointed out, by means of a neat algebraic formulation, that Fisher's fundamental theorem of natural selection does not apply exactly in a discrete-generation random-mating situation unless there is no dominance in fitness, and that the mean fitness cannot decrease from generation to generation for a single diallelic locus.

Li writes, "Fisher obtained his result on the basis of a continuous time model with logarithmic fitness", but it should be added that Fisher<sup>2-4</sup> never suggested that his theorem should be applied to discrete-generation models; indeed, he most carefully stipulated, in the sentence following his original formulation<sup>2</sup>, that "the rigour of the demonstration requires that the terms employed should be used strictly as defined". In particular, time was to be taken as continuous, and fitnesses were to be measured by Malthusian parameters of population increase. It is thus a misrepresentation to refer to any discrete-generation formulation as "Fisher's fundamental theorem".

These remarks should not be taken to imply that the interpretation of the fundamental theorem, correctly formulated, is simple. A further condition was later introduced by Fisher<sup>3</sup> and discussed by Kempthorne<sup>5</sup>. Kimura<sup>6</sup> has given a very general formulation, which Mode<sup>7</sup> has extended to the stochastic case. Several points remain to be cleared up and I shall examine them elsewhere<sup>8</sup>.

With regard to Li's second point, that in the discrete-generation model the mean fitness for a diallelic locus cannot decrease, it should be noted that this has already been proved by Moran<sup>9</sup>, and for any number of alleles by several investigators<sup>10-13</sup>. The fact that the general theorem preceded the special theorem for two alleles is due to the latter having been assumed for many years to be an obvious consequence of Wright's formulation<sup>14</sup>. In fact, as Moran<sup>9</sup> mentioned, monotonic convergence of the

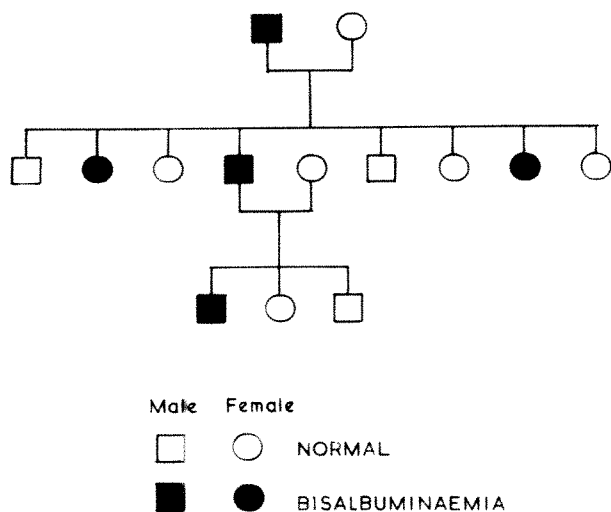

Fig. 1. Family tree.

gene frequency must be proved, and not assumed. Cannings has pointed out to me that in the case of heterozygote advantage monotonic convergence is implicit in Fisher's original treatment<sup>2</sup>. This property of the mean fitness should not, at the present state of our knowledge, be taken as a manifestation of any supposed fundamental theorem in discrete time.

## HAEMATOLOGY

### Use of Human Lymphocytes in Studies of Drug Action

LYMPHOCYTES from venous blood synthesize immunoglobulins<sup>1</sup> and a wide range of other proteins<sup>2</sup>. Lymphocyte suspensions are a useful preparation for studying the effects of drugs on protein synthesis *in vitro*. Their value has been enhanced by using a medium free of plasma, so that substances in the plasma which affect protein synthesis<sup>3</sup> can be avoided. Also interactions of drugs with plasma proteins are avoided; alternatively it is possible to detect modifications of the effects of drugs by substances present in the plasma.

Lymphocyte suspensions were prepared by a modification of the method of Rabinowitz<sup>4</sup>, using cotton instead of glass wool. The cells were washed twice with Hanks balanced salt solution before suspension in culture medium (Eagle's medium<sup>5</sup> made up without leucine, and supplemented with "non-essential" amino acids, as described by Ambrose<sup>6</sup>). Triplicate cultures were set up with  $1-4 \times 10^6$  lymphocytes and  $0.25 \mu\text{C}$ .  $^{14}\text{C}$ -leucine (specific activity  $150 \text{ mc./mmole}$ ) in  $1 \text{ ml.}$ , for  $24 \text{ h.}$  To measure protein synthesis plasma was added, precipitated and washed with trichloroacetic acid, and its radioactivity was determined.

The plateau effect frequently seen with increasing concentrations of drug is illustrated in Fig. 1. Many drugs did not suppress the protein synthesis by lymphocytes *in vitro*. Cyclophosphamide, a drug which has been shown to inhibit immune responses *in vivo*<sup>7</sup> but is inactive *in vitro*<sup>8</sup>, was ineffective at concentrations up to  $160 \mu\text{g/ml.}$  No significant inhibition was observed in the presence of chloramphenicol at concentrations up to  $640 \mu\text{g/ml.}$  Salicylate ( $500 \mu\text{g/ml.}$ ) inhibited protein synthesis five times out of six, whereas *para*-hydroxybenzoate had no effect (Fig. 1). Two purine analogues, 6-mercaptopurine and azathioprine, inhibited significantly (25–75 per cent). Azathioprine ( $60 \mu\text{g/ml.}$ ) inhibited approximately twice as much as 6-mercaptopurine. Lymphocyte protein synthesis was completely abolished by puromycin, and actinomycin D immediately inhibited all but a small fraction of synthesis, which ceased after 6 h.

The inhibition by hydrocortisone may be related to its immunosuppressive effects. Hydrocortisone was inhibitory even at a very low concentration, an effect which seems to be at variance with the finding of Ambrose<sup>9</sup> that it is essential for antibody synthesis by fragments of rabbit lymph nodes. Chloramphenicol inhibits antibody synthesis in Ambrose's system<sup>9</sup>. These discrepancies have been resolved to some extent by subsequent studies of Ambrose which show that hydrocortisone and chloramphenicol exert their greatest effect during the inductive phase of the secondary immune response<sup>10</sup>. These substances had little effect on the established response. It is therefore possible that these drugs are effective on cells other than lymphocytes in Ambrose's system.

Synthesis of protein is stimulated 2.5–4 times by phytohaemagglutinin (PHA) in this system. The degree of inhibition of protein synthesis by all of the drugs used in these experiments was of the same order in the presence of PHA as in cultures without PHA.

The inhibition of protein synthesis by drugs in a medium free of plasma may be caused simply by the death of cells under these conditions. It was shown, however, that lymphocytes survived as well in the presence of concentrations of salicylate, hydrocortisone and chlorambucil which depressed protein synthesis significantly, as in the absence of these drugs. By contrast indomethacin killed most of the cells within 24 h (Fig. 2).

The inhibitory effect of drugs on protein synthesis may be modified by the presence of plasma. Synthesis in cultures free of plasma which contained drug was com-

Fig. 1. Inhibition in the presence of increasing concentrations of indomethacin (IND), salicylate (SAL), hydrocortisone succinate (COR) and chlorambucil (CHL). The isomer of salicylate, *p*-hydroxybenzoate (p.OH-B), caused no significant depression of protein synthesis. Triplicate cultures set up in each experiment contained no drug. Protein synthesis in these cultures is represented as 100 per cent activity.

Fig. 2. Curves showing the survival of lymphocytes in cultures with a medium free of plasma. Survival was measured by counting the cells at intervals in a Coulter counter and determining viability by observing their ability to exclude trypan blue. The survival in the presence of salicylate, hydrocortisone and chlorambucil was not significantly reduced below that seen in control cultures. In contrast indomethacin was highly cytotoxic. Concentrations of drugs used were: indomethacin (IND) 40  $\mu\text{g}/\text{ml}$ ., salicylate (SAL) 500  $\mu\text{g}/\text{ml}$ ., hydrocortisone succinate (COR) 1  $\mu\text{g}/\text{ml}$ ., chlorambucil (CHL) 4  $\mu\text{g}/\text{ml}$ .

Fig. 3. Showing the inhibition of protein synthesis by lymphocytes by drug in medium free of plasma (●), and in medium containing 25 per cent autologous plasma (○). Lines join paired observations on lymphocytes cultured simultaneously from the same donor.

pared with synthesis in cultures in medium containing drug and 25 per cent autologous plasma (Fig. 3). The reduced potency of indomethacin, hydrocortisone and chlorambucil is probably caused by binding of drugs by plasma, which reduces their effective concentration in the medium. Oxyphenbutazone is known to be bound to plasma proteins<sup>10</sup>. When concentrations of this drug were increased to levels of 560  $\mu\text{g}/\text{ml}$ , the suppression of protein synthesis was similar to that caused by a concentration of 56  $\mu\text{g}/\text{ml}$  in medium free of plasma.

The mode of action of anti-inflammatory drugs is little understood. Auto-immune mechanisms, mediated by lymphocytes, are held to play a part in some of these diseases, such as rheumatoid arthritis. These data focus attention on the effects of anti-inflammatory drugs on cells of the lymphoid system. Of course, the effect *in vivo* may not be of the same order as that seen *in vitro*, but it is interesting that 6-mercapto-purine and azathioprine, which inhibit the homograft reaction<sup>7</sup>, are effective inhibitors of lymphocytes *in vitro*.

Screening for capacity to inhibit protein synthesis by lymphocytes may be a useful procedure in selecting drugs for both anti-inflammatory and immunosuppressive activity.

## IMMUNOLOGY

### Modification of the Skin Allograft Response across the *H-2* Locus by Pre-treatment with Transplantation Antigens

WE have investigated whether or not pre-treatment with a sub-cellular fraction containing transplantation antigens can increase survival of skin allografts across the *H-2* histocompatibility locus in inbred adult mice. Graft survival was assessed by histological scoring at a standard time interval, rather than by relying on cross evaluation of graft rejection. Congenic resistant strains of mice were used so as to minimize non-*H-2* antigenic disparity between donor and recipient. *C57BL10/SnJ* mice (*H-2<sup>b</sup>*) were used as donors of antigen and skin, and *B10D2/SnJ* mice (*H-2<sup>d</sup>*) as recipients. All mice were obtained from the Jackson Laboratory, Bar Harbor, Maine, and were males between 10 and 30 weeks of age.

Antigenic extracts were prepared from lymphoid tissue by a modification of the magnesium-sucrose method of Mann *et al.* (unpublished results). Donors were killed by cervical luxation, and spleen, thymus, mesenteric, cervical and axillary lymph nodes were rapidly removed and immersed in cold Ringer's lactate solution. The tissues were washed in cold magnesium-sucrose solution (0.25

molar sucrose, 0.03 molar potassium chloride, 0.0005 molar magnesium chloride and 0.01 molar *tris-tris*-chloride, pH 8.0 at 5° C), cut into fragments, pressed through a 40 mesh stainless steel screen, and suspended in magnesium-sucrose solution in volume of 3–6 ml./donor. The suspension was dispersed in a glass hand homogenizer with 0.002 in. clearance and centrifuged at 1,500*g* max. for 15 min. The supernatant was centrifuged at 5,000*g* max. for 10 min, and the supernatant from this step was centrifuged at 105,000*g* max. for 1 h. The sediment of this last step, later used as the antigenic fraction, was resuspended in *tris* buffer (0.01 molar *tris-tris*-chloride, 0.0005 molar magnesium chloride, pH 8.0 at 5° C), freeze-dried, and stored at –20° C. The freeze-dried antigenic fraction, resuspended in 1 ml. of *tris* buffer, was injected intraperitoneally into prospective test graft recipients. A single injection of 1.6 mg given intraperitoneally 4 days before grafting was a moderately effective sensitizing dose (mean epithelial survival of 16 per cent at 6 days, *n*=11). Greater epithelial survival was seen after administration of either smaller or much larger doses.

Prospective recipients of graft were injected intraperitoneally with a large or small dose (8 mg or 8 µg) of the antigenic fraction on 6 days a week. After 3 weeks of pre-treatment, a test skin graft 1 × 1 cm was placed on the lateral chest wall. Antigenic injections were continued for 10 days. The grafts were then excised, and the raw graft bed was re-grafted with syngeneic skin to facilitate healing. Injections were continued one a week for 4 weeks after excision of the first-set grafts. The mice then received a second test graft on the contralateral chest wall. These grafts were also excised after 10 days. After excision, all skin grafts were fixed in 10 per cent formalin, processed, cut in six to nine planes and stained with haematoxylin and eosin. Grafts were coded, and epithelial survival was assessed histologically without knowledge of the origin of the graft. Criteria previously described for histological assessment of skin allografts were used<sup>1</sup>, but required modification because of the 10 day survival interval used in these studies. Grafts were assigned an epithelial survival percentage of 100, 90, 75, 50, 25, 10 or 0 based on microscopic examination.

Table 1. EFFECT OF HIGH AND LOW DOSE ANTIGENIC PRE-TREATMENT ON HISTOLOGICAL SURVIVAL OF *H-2* INCOMPATIBLE SKIN ALLOGRAFTS AT 10 DAYS (C57BL10/*SnJ* → B10D2/*SnJ*)

First-set skin grafts: recipients received intraperitoneal injections six times a week for 3 weeks before skin grafting.

Group	Injection	Epithelial survival percentage	Mean epithelial survival percentage
1a	8 mg of Antigen/ 1 ml. of <i>tris</i>	25, 25, 50, 50, 75	45
2a	8 µg of Antigen/ 1 ml. of <i>tris</i>	25, 50, 50, 75, 75, 90, 90	65
3a	1 ml. of <i>tris</i>	0, 0, 0, 25, 25, 25, 25	14

Second-set skin grafts: after excision of first-set grafts, intraperitoneal injections were continued once a week for 4 weeks and a second skin allograft applied.

Group	Injection	Epithelial survival percentage	Mean epithelial survival percentage
1b	8 mg of Antigen/ 1 ml. of <i>tris</i>	0, 50, 75, 90	54
2b	8 µg of Antigen/ 1 ml. of <i>tris</i>	0, 0, 10, 25, 25, 50, 75, 90	34
3b	1 ml. of <i>tris</i>	0, 0, 0, 0, 0, 0, 0	0

Three mice were lost from peritonitis (two in Group 1a and one in Group 1b). Two mice died from intraperitoneal bleeding after injection (one each in Groups 1a and 3b). Two mice were excluded because of technical failures in grafting (one each in groups 2a and 3a).

Results are shown in Table 1; mice which received either large or small doses of antigen showed an increase in first-set graft survival. This was particularly striking in the low dose group (*P* < 0.001 for Group 2a, as compared with control Group 3a). Improved survival of second skin grafts was also seen in all animals which received antigenic pre-treatment (*P* < 0.05 for Group 1b as compared with control Group 3b and *P* < 0.02 for Group 2b, as compared with 3b). The improved first-set

graft survival seen after injection of a small dose (2a) has since been confirmed in further experiments, but smaller doses of antigen (0.8 µg) have not resulted in increased allograft survival.

Previous attempts to induce tolerance across the *H-2* locus solely by antigenic extracts have generally been unsuccessful, although Martinez reported occasional striking prolongation of graft survival using massive doses of antigen<sup>2</sup>. Attention in the current experiments was focused on small doses of antigen, based in part on the results reported by Dresser<sup>3</sup> and Michison<sup>4</sup> using soluble non-transplant antigens (bovine serum albumin and bovine gamma globulin). The results reported here suggest that small doses of predominantly particulate transplantation antigens can diminish the host immune response to a test graft.

In summary, the survival of skin allografts has been increased in adult mice differing at the *H-2* locus by repeated intraperitoneal injections of either small or large doses of an allogeneic antigenic fraction. Graft survival was increased even after a strongly sensitizing stimulus in the form of a previous skin graft.

### Monotypic Cold Agglutinins in Infection by *Mycoplasma pneumoniae*

ISOLATED cold agglutinins from patients with chronic idiopathic autoimmune haemolytic anaemia are macroglobulins, the majority of which have type-K and the minority type-L light chains<sup>1,2</sup>. Because they are homogeneous in individual patients with respect to their light chain types they resemble the "paraproteins".

Transient elevations of cold agglutinin titre occur in association with *Mycoplasma pneumoniae* infection<sup>3</sup>. Although overt haemolytic anaemia is uncommon in such situations<sup>4</sup> a transient autoimmune haemolytic anaemia can occasionally occur<sup>5</sup>. Transient post-infective cold agglutinins would be expected to be heterogeneous with respect to their light chain types. In twenty out of thirty isolated transient cold agglutinins so far reported in patients with *M. pneumoniae* infection or atypical pneumonia, both types of light chain were detected<sup>6-8</sup>. One type of light chain (either type-K or type-L) was detected in the remaining ten but their homogeneity was not definitely established<sup>6,8</sup>.

Ten cold agglutinins from patients with respiratory infections have been isolated by a thermal elution method<sup>9</sup> and their light and heavy chain types determined by the Ouchterlony technique in agar gel plates using anti type-K and anti type-L antisera provided by Dr J. Fahey and antisera to IgG, IgA and IgM obtained from the Netherlands Red Cross Laboratories. With one exception these were transiently elevated cold agglutinins, eight of which were associated with *M. pneumoniae* infection

Table 1. LIGHT CHAIN TYPES OF TEN ISOLATED IgM COLD AGGLUTININS FROM PATIENTS WITH RESPIRATORY INFECTIONS

Clinical picture	No. tested	Light chain types detected	
		K	K+L
<i>Mycoplasma pneumoniae</i> infection without anaemia	4	—	4
<i>Mycoplasma pneumoniae</i> infection with transient autoimmune haemolytic anaemia	4	3	1
Atypical pneumonia (cause not established) with transient autoimmune haemolytic anaemia	1	1	—
Chronic autoimmune haemolytic anaemia presenting after atypical pneumonia (cause not established)	1	1	—

(Table 1). The diagnosis of *M. pneumoniae* infection was based on a four-fold or greater increase in complement fixing antibody titre against this organism or a titre of 256 or greater during a respiratory infection. Tests for complement fixing antibodies against the antigens of *Rickettsia burneti* and the following virus antigens were negative: adenovirus, psittacosis, influenza A, B, and C, parainfluenza 3, respiratory syncytial, and sendai (parainfluenza 1). In four cases there was no anaemia; in five cases there was transient autoimmune haemolytic anaemia; in one case an episode of atypical pneumonia (aetiology not established) was followed by chronic unremitting autoimmune haemolytic anaemia.

All ten cold agglutinins were of anti-I specificity<sup>10</sup>; they were IgM antibodies forming precipitin lines with antiserum to IgM and not with antisera to IgG or IgA as in Fig. 1. The concentrations of IgM in the isolated cold agglutinin solutions ranged from 0.1 to 0.3 mg/ml. as determined by radial immunodiffusion (Hyland Immunoplates).

Fig. 1. Ouchterlony test with an isolated cold agglutinin (centre) from a patient with *Mycoplasma pneumoniae* infection and no anaemia, showing a precipitin line with antiserum to IgM but not with antisera to IgG or IgA.Fig. 2. Demonstration of type-K and type-L ( $\lambda$ ) light chains in an isolated IgM cold agglutinin (centre) from a patient with *Mycoplasma pneumoniae* infection and no anaemia.Fig. 3. Isolated cold agglutinin (centre) from a patient with *Mycoplasma pneumoniae* infection and transient autoimmune haemolytic anaemia, showing precipitin lines with antisera to IgM and type-K light chains but not with antiserum to type-L ( $\lambda$ ) light chains.Fig. 4. Isolated cold agglutinin (centre) from a patient with chronic autoimmune haemolytic anaemia presenting after atypical pneumonia (cause not established) showing precipitin lines with anti IgM and anti type-K antisera but not with anti type-L ( $\lambda$ ).

In the Ouchterlony tests the antigen wells were refilled three times with the more concentrated eluates and up to eight times with the more dilute ones. In this way approximately equal amounts of IgM were present in the various antigen wells. Both types of light chain were detected in all four of the transient cold agglutinins associated with *M. pneumoniae* infection without anaemia and in one of the four patients with this infection complicated by transient autoimmune haemolytic anaemia (Table 1, Fig. 2). There was no indication that the K and L determinants were present in the same molecules (as suggested by Costea *et al.*<sup>7</sup>) in so far as the precipitin lines with anti type-K and anti type-L antisera crossed one another without partial merging. In three of the four cases in whom the *M. pneumoniae* infection was complicated by transient autoimmune haemolytic anaemia and in the two cases with haemolytic anaemia (one transient and one chronic) in whom the aetiology of the pneumonia was not established, type-K light chains only were detected (Figs. 3 and 4).

Increase in cold agglutinin associated with *M. pneumoniae* infection is probably an indirect rather than a direct effect of the infection<sup>11</sup>. Whatever the mechanism of production of cold agglutinins with this infection, the finding of exclusively type-K light chains in some of them is interesting. It is not known whether such monotypic, post-infective cold agglutinins can, in some cases, persist; the observations in the last case (Table 1) indicate that such a possibility exists.

I thank Dr J. Fahey for the antisera to type-K and type-L light chains, Professor J. V. Dacie and Drs D. Garrow and H. P. Lambert for sera from patients with high titre cold agglutinins, Dr R. G. Sommerville for the mycoplasma and virus complement fixation tests, Mr C. Gilson and the staff of the Royal Free Hospital photographic department for their assistance.

This work was supported by grants from the Royal Free Hospital and the Medical Research Council.

## PHYSIOLOGY

### Liebreich's Sign for Defective Colour Vision among Artists

LIEBREICH<sup>1</sup> pointed out that in a London exhibition of 1871 a painting showed roofs an oxen red on the sunny side but green where shadowed. He suggested that it indicated that the painter was a red-green colour vision defective. Angelucci<sup>2</sup> called this "Liebreich's sign" when he described the works of six painters known to be red-green defectives, whose pictures showed this characteristic. Trevor-Roper<sup>3</sup> and Kalmus<sup>4</sup> also mention Liebreich's sign.

I have examined a number of paintings by the red-green defective artists mentioned elsewhere<sup>5-8</sup>, and by six of the art students discussed later<sup>9</sup>, together with paintings by seven more art students. The resulting data are shown in Table 1, each type of defective being noted separately. Of the ninety-eight pictures which did not show Liebreich's sign twelve had no shadows because they were abstract designs. Liebreich's sign is not more often shown by deuterans than by protans because the observed difference is not statistically significant.

Table 1

Type	Artist	No.	No. of pictures	Liebreich's sign	
				+	-
DA	5	39	6	33	
EDA	5	25	4	21	
D	1	5	2	3	
Totals	11	69	12	57	
PA	2	19	0	11	
EPA	5	17	7	10	
P	1	12	1	19	
Totals	8	48	8	40	
Undiagnosed	1	1	0	1	
Grand totals	20	118	20	98	

Among six paintings reproduced in colour by Rabkin<sup>10</sup>, which are copies by red-green defectives of other pictures also shown, only Plate 4, by a deuteranomal, and Plate 6, by a protanomal, show Liebreich's sign. In Plate 10 a green shadow in the original has been more emphasized in the copy by a protanomal, while in Plate 12 green shadows of the original have become brown in the copy by a deuteranomal.

It appears that Liebreich's sign is sometimes present in the paintings of red-green colour vision defectives, but, at least in contemporary artists and students of art, it is too infrequent to be a reliable guide.

### Effect of Laparotomy on Plasma Renin Activity in the Rabbit

WHILE trying to find an effective stimulus for the release of renin in the rabbit, we inserted a catheter into the left lumbo-adrenal artery and pushed the tip into the left renal artery close to the kidney. With no further manipulation the plasma renin activity increased within a few hours and subsequently fell to normal or less than normal values during the next few days. This unexpected observation encouraged us to investigate the changes in plasma renin brought about by opening the abdomen.

Eight rabbits were anaesthetized with 30 mg/kg of sodium pentobarbitone given intravenously. A 4-in. incision was made in the midline of the abdomen and the peritoneum was opened. The incision was covered with gauze swabs soaked in warm saline. After 20 min the abdomen was closed in two layers, and blood samples were taken by puncture of the central artery of the ear. Three samples were taken from each animal: after anaesthesia but before incision; 4 h after incision; and 48 h after the first sample. The volume of blood taken was 4.5 ml. with 30 U of heparin/ml. to prevent clotting. A normal diet with free access to water was allowed before and after operation. For comparison arterial blood samples were taken from four rabbits at time intervals which were the same as for the operated animals, but these rabbits were not anaesthetized nor were they operated on. A further four rabbits were anaesthetized and blood samples were taken at similar intervals.

Plasma was separated by centrifugation and assayed by a method described in more detail elsewhere<sup>1</sup>. Each sample of plasma was treated in the following way: 2 ml. of plasma was added to 1.0 ml. of soybean trypsin inhibitor (1 mg/ml.). To this mixture was added 1.0 ml. of  $4 \times 10^{-2}$  molar disodium ethylene diamine-tetraacetic acid (EDTA), and 0.1 ml. of  $4 \times 10^{-1}$  molar dimercaprol, which was in arachis oil. Soybean trypsin inhibitor and EDTA were in 0.1 molar sodium phosphate buffer, pH 6.0, containing chlorhexidine gluconate, 0.01 per cent w/v. The EDTA, dimercaprol and chlorhexidine inactivate plasma angiotensinases, and soybean trypsin inhibitor prevents the formation of plasma kinins. To this buffered plasma mixture was added sufficient renin substrate to give a final substrate concentration of 900-1,000 µg/ml. The final mixture was incubated for 6 h at 42° C. The supernatant collected after snap freezing or heating at 100° C was assayed to find the concentration of angiotensin.

Renin substrate was prepared from plasma of rabbits 48 h after bilateral nephrectomy. Ammonium sulphate was added to the plasma to 60 per cent saturation. The precipitate was separated by centrifugation and redissolved in a quarter the volume of distilled water. This

solution was dialysed at 4°C first against distilled water containing 0.01 per cent chlorhexidine gluconate for 24 h and then against  $3 \times 10^{-3}$  molar EDTA, also containing chlorhexidine, for a further 24 h. The clear, faint brown solution was used as renin substrate.

Plasma renin activity was estimated in the anaesthetized ganglion blocked rat<sup>2</sup> by direct comparison of the amount of angiotensin formed in the reaction mixture against the total substrate angiotensin available. We have defined for this reaction an arbitrary unit (our unpublished results)<sup>2</sup>. One unit is that net enzyme activity causing the release of 1 per cent of the angiotensin content of substrate in 1 h at 42°C when the initial concentration of substrate is within the first order range.

Table 1. EFFECT OF LAPAROTOMY ON PLASMA RENIN ACTIVITY

Rabbit No.	Control (U/ml.)	4 h (U/ml.)	48 h (U/ml.)
1	3.3	10.0	2.7
2	4.7	14.6	2.8
3	1.3	8.0	1.3
4	4.0	14.4	3.3
5	2.7	9.2	3.3
6	3.3	7.7	2.5
7	3.3	13.3	2.5
8	2.2	5.3	2.5

Mean plasma renin, controls = 3.1 U/ml. ( $\pm 0.42$  standard error)

Mean plasma renin at 4 h = 10.3 U/ml. ( $\pm 1.21$  standard error)

Mean plasma renin at 48 h = 2.6 U/ml. ( $\pm 0.22$  standard error)

By Student's paired *t* test the mean increase between the control group and the 4 h group is very significant ( $P < 0.01$ ). By the same test the decrease at 48 h was not significant.

Table 2. PLASMA RENIN ACTIVITY DURING SAMPLING AND ANAESTHESIA

Sample	Sampling only (4) mean (U/ml.)	Anaesthesia (4) mean (U/ml.)
Control	2.0 (4)	1.9 (4)
After two or three samples at 30-min intervals	2.3 (4)	1.8 (4)
4 h after control sample	2.4 (4)	1.2 (2)
2 days after control sample	1.8 (4)	1.6 (3)

Numbers in brackets indicate the number of rabbits in each group.

The effect of opening the abdomen is shown in Table 1. Plasma renin activity increased on average three-fold in 4 h. By 48 h plasma renin activity had returned to control levels and in five out of eight animals it was less than the control values.

Systolic blood pressure was measured using the Grant-Rothschild ear capsule in six rabbits which had been subjected to operation. In no case did the pressure fall to less than the pressure observed before anaesthesia, and never was it less than 80 mm of mercury. Sampling and anaesthesia produced no significant change in plasma renin activity, which confirmed previous observations<sup>3</sup> (Table 2). A feature of the control experiments was the remarkable constancy of plasma renin activity in a particular healthy rabbit although renin activity varied widely from rabbit to rabbit.

These results indicate that laparotomy causes a marked increase in plasma renin activity. Such change is in contrast to the results in rabbits subjected only to blood sampling and anaesthesia. The mechanisms involved in the changes in renin activity with operation are obscure. The increase in plasma renin activity seems to be too prolonged to be associated with the small systemic changes in blood pressure seen during operation. Opening the abdomen could act as a form of decompression stimulating a baroreceptor mechanism which in turn reduces renal blood flow. For example, a decrease in pressure in the superior mesenteric artery has been shown to produce reflex vasoconstriction in the cat<sup>4</sup> and dog<sup>5</sup>.

Increased plasma renin activity could stimulate the secretion of aldosterone leading to post-operative sodium retention<sup>6,7</sup>. Laparotomy in the anaesthetized dog has

produced a four-fold increase in secretion of aldosterone<sup>8</sup>. There are high concentrations of aldosterone in the plasma of the adrenal vein in man during operation<sup>9</sup>. Spironolactone has been shown to suppress almost completely post-operative sodium retention<sup>10,11</sup>.

Clearly future experiments on renin and aldosterone which require intra-abdominal manipulation should take into account the acute increase of plasma renin activity produced by laparotomy alone.

## Fluid Dynamics of Excretion in *Anodonta*

URINE is produced in the bivalve mollusc *Anodonta* by the filtration of blood plasma into the pericardium and the pericardial fluid so formed is directed into the renal organs by the cilia of the reno-pericardial funnels<sup>1</sup>. The output of urine from the external urinary pore was until recently considered to be caused by filtration pressure and ciliary action. Trueman<sup>2</sup>, however, confirms the hypothesis of Ramsay<sup>3</sup> and Krijgsman and Divaris<sup>4</sup> that a negative pressure tends to occur in the pericardium at systole and suggests that the suction produced favours auricular filling. This suction would also oppose the flow of urine through the renal organs. Using transducers to record pressures in the pericardium and haemocoel of various bivalves, Trueman<sup>2,5</sup> has shown that there are considerable hydrostatic pressures corresponding to adduction of the shell and has established that there is a pressure gradient between the pericardium and the mantle cavity immediately after adduction. The possibility of these pressure gradients being involved in the mechanism of urine flow in *Anodonta* prompted this investigation.

Simultaneous pen recordings of pressures in the pericardial cavity, mantle cavity and renal organs, and of movements of the shell were obtained by the use of two Statham 'P23BB' pressure transducers (maximum sensitivity 0.4 cm water/cm pen deflection) and of an isotonic myograph. The cannulae, No. 16 hypodermic needles, were carefully inserted through small holes in the shell valves until satisfactory recordings were obtained, whereupon they were firmly fixed in position with wax. After recording, the locations of the cannulae were checked by dissection.

On adduction of the shell valves, simultaneous pressure peaks of equal amplitude were recorded from the pericardial cavity and mantle cavity (Fig. 1A). The amplitude of the pressure recorded from the renal bladder on adduction was, however, equivalent to about one-fifth of those of the pericardial and mantle cavities, though of similar duration to that of the pericardial cavity (Fig. 1B). Secondary peaks of longer duration and smaller amplitude followed in specimens where the foot was originally extended, coinciding with pedal retraction (Fig. 2).

To substantiate these results, the urinary pore of one side of *Anodonta* was displayed by the removal of a small square of shell and tissue. To aid observation, a little pericardial fluid was withdrawn and replaced by an equivalent quantity of starch in isotonic saline to which a few drops of iodine solution had been added. It was then possible, after allowing a sufficient period for the dye to distribute throughout the renal system, to observe the actual excretion of urine by the appearance of the blue fluid through the urinary pore. During periods of siphoning with the valves gaping widely, the urinary pore could be observed to be occluded by its sphincter muscle, occasionally opening briefly to allow a slight outflow of urine. Adduction of the shell valves resulted in a jet of urine being expelled through the urinary pore which ceased whenever pedal retraction took place.

The morphology of *Anodonta* (Fig. 3) implies that the increase in pericardial pressure at shell closure must effect a change in pericardial shape, either as the contraction of the heart and rectum or by the ventral displacement of the renal organs which lie immediately below the floor of the pericardium. Because natural adductions invariably occur during systole (Fig. 4), the ventricle is unlikely to be effective in buffering much of the force produced by further contraction but the rectum probably undergoes compression. Ventral displacement of the pericardial floor together with the lateral force imparted

Fig. 3. Diagrammatic transverse section of *Anodonta* with valves adducted showing the probable effect of adduction on the pericardium. The dotted lines represent the original position of the shell valves before adduction and the large arrows indicate the effect of the pressure at adduction. *a*, Auricle; *b*, renal bladder; *f*, foot; *g*, glandular region of the renal organ; *ig*, inner gill; *l*, ligament; *m*, mantle; *mc*, mantle cavity; *og*, outer gill; *pc*, pericardial cavity; *r*, rectum; *rpo*, reno-pericardial opening; *s*, shell; *sc*, suprabranchial cavity; *up*, urinary pore; *v*, ventricle.

Fig. 1. Recordings demonstrating the relationship, at adduction, between pressures (in cm of water) in the mantle cavity and (A) the pericardium and (B) the renal bladder.

Fig. 2. Recording of the pericardial pressure, upper trace, showing peaks caused by adduction (*a*) and by pedal retraction (*pr*). Shell movements are also recorded, (*o*) indicating valves maximally open and (*c*) completely closed.

Fig. 4. Recording of pressure changes in the pericardium. The negative pressures (*s*) correspond to systole; the large peak (*a*) is brought about by adduction at systole.

on the bladder by the closing of the shell valves will apply an external force on the fluid within the renal organs which will produce a pressure gradient between the bladders and the suprabranchial cavities of the inner gill lamellae. This occurs because the positive pressure in the mantle cavity returns more rapidly to normal after adduction than does that in the pericardium and renal bladders because there is no ventral fusion of the mantle lobes in *Anodonta*, the mantle cavity being continuously open to the exterior (Fig. 1A and B). Opening of the urinary pores occurs at adduction and to equilibrate the pressure gradient urine is ejected under pressure into the suprabranchial cavities to be voided through the exhalant siphon. Pericardial fluid may also pass at adduction, under pressure, into the glandular parts of the renal organs through the reno-pericardial openings, but the resistance to flow in this region may be great because of the convoluted nature of the glandular epithelium.

Shell and pedal movements resulting in an increase in tone of the general body musculature are shown to play a significant part in the excretion of urine in the freshwater mussel *Anodonta*. Indeed, shell movements occur with sufficient frequency that they may well prove to account for most of the urine excreted. Further experiments are required to ascertain whether there is any direct relationship between shell or foot movements and osmotic regulation.

This investigation was carried out during the tenure of a research studentship of the Science Research Council. I thank Mr E. R. Trueman for his interest, help and

encouragement during the course of this study and in the preparation of the manuscript.

### Ganglion Cells in the Frog Retina: Inhibitory Receptive Field and Long-latency Response

The ganglion cells of the frog retina can be sub-divided into different functional classes<sup>1</sup>. When investigated under light adapted conditions, class I cells (sustained edge detectors) respond to sharp edges moving through their receptive field, giving a stronger response when the object causing the edge is small than when it is large. A sustained response occurs when an edge is stopped within the field. In darkness, with a standing edge present in the receptive field, a response can be elicited by turning on the light or by a short flash of light.

Our investigation examines the properties of class I cells in dark adapted conditions with non-moving stimuli. Varying the intensity of light flash stimuli we found that the latency of the spike response becomes longer with increasing light intensities, the delays becoming abnormally long under certain conditions. A simple empirical equation adequately describes the relationship between light intensity and latency.

European water frogs, *Rana esculenta*, were immobilized with curare and given xylocain for local anaesthesia so that the optic tectum could be surgically exposed. Using metal filled microelectrodes, spikes were recorded from the terminal endings of class I axons in the outer layers of the exposed tectum (right hemisphere). The contralateral (left) eye faced the stimulus pattern (the ipsilateral eye was covered) and the frog was dark adapted for at least 30 min before measurements were taken. The experiments were carried out at room temperature, which ranged between 23° and 27° C. The stimulus pattern consisted of a stationary circular black disk against a matt white paper background with a contrast ratio of 1:10, centred in the receptive field 25 cm from the eye. According to Grüsser *et al.* (personal communication) an object at this distance will be in focus for curarized frogs. The diameter of the black disk subtended a visual angle of 5° from the eye. A stroboscope supplied single light flashes of high intensity with a half width of 50  $\mu$ sec. The peak intensity ( $I_0$ ) of the flash was 40,000 lux, as measured in a plane across the frog's eye, and neutral density filters were used to vary the intensity.

Readings were taken from thirteen cells in six different frogs, and a total of 149 measurements were made. After each light flash there followed a "rest period" of at least 60 sec before the next stimulus. As long as the rest period was greater than 30 sec the measured latency was

independent of the previous flash. The series of light flashes were given both in order of increasing and of decreasing intensities; the results did not differ. Fig. 1 *a-f* shows the results for one cell for six different intensities of flash. In this initial report only the latency between stimulation and the onset of firing will be considered; other parameters such as frequency and total activity have not yet been quantitatively investigated. In this case, at the lowest light intensity ( $I/I_0 = 0.0032$ ), the cell responded 1.2 sec after stimulation. As the intensity is increased the latency becomes progressively longer so that at the greatest intensity ( $I/I_0 = 1.0$ ) a delay of 13 sec is observed between the application of the light flash and the onset of major activity of the cell. Occasionally, one or two spikes can be seen during the first second after the stimulus.

When intensity and latency are plotted logarithmically, the relationship displayed in the graph in Fig. 1 is seen. The points represent each of the measurements made on the thirteen cells and the heavy unbroken line is a curve described by a power function of the form  $T = kI^\alpha$ , where  $k$  and  $\alpha$  are constants,  $T$  is latency and  $I$  is intensity. This line fits the experimental results within the intensity range investigated. It represents the least square fit applied to the logarithms of  $I$  and  $T$ , with resulting values for the constants of  $k = 10.1$  and  $\alpha = 0.36$ . The other lines represent those individual curves which have extreme values of  $k$  and  $\alpha$ . The two dashed lines show the consecutive measurements made on each of two different cells which had the largest (maximal and minimal) deviations from the average value of  $k$ . The two unbroken (thin) lines are correspondingly drawn through points from two cells with the largest deviations from the average slope.

The size of the stimulus disk affects the total number of spikes and the rate of spike discharge. We used the 5° disk because it produced more spikes at a given intensity than smaller or larger disks. Furthermore, we found a spatial organization of the receptive field. In order to evoke activity with a light flash it was necessary for a contrast to be present in the central excitatory part of the receptive field (ERF), whereas, when additional

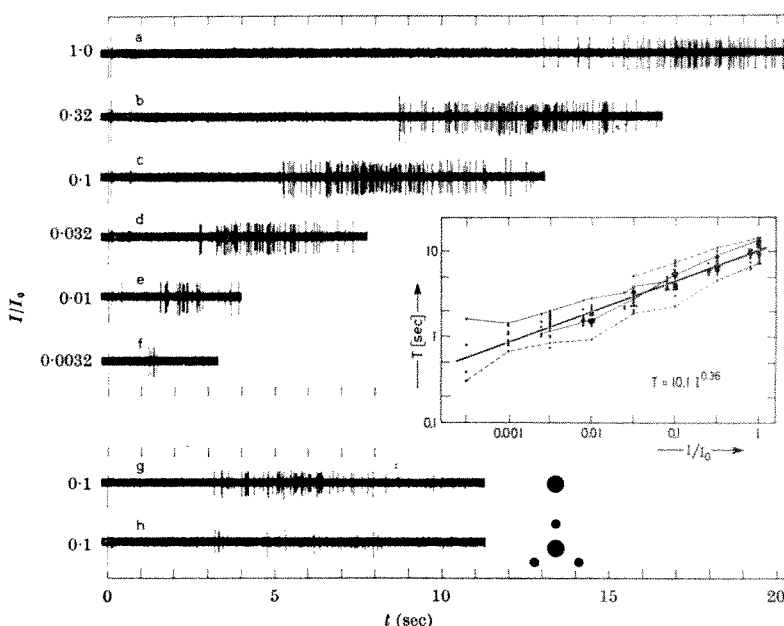

Fig. 1. Class I neurones. Records *a-f*: responses of one cell to short flashes of light of varying intensity, when a 5° black disk is placed against a white background and centred in the receptive field. First spike: stimulus artefact. The numbers to the left indicate the flash intensity in relative units. Records *g* and *h*: response of another cell to flashes of light of the relative intensity 0.1. Stimulus pattern as indicated to the right. Inset: the latency (in seconds) between stimulus and onset of spike response plotted versus the intensity of flash stimuli (in relative units). Data obtained from thirteen different cells. Lines drawn across the points are explained in the text.

contrasts were present in the area surrounding the ERF, the activity of the cell was reduced. This inhibition is thus seen only as a diminution of activity already evoked by a contrast in the ERF proper. An example of this effect is shown in records *g* and *h* of Fig. 1. Record *g* shows the response of the cell to a light flash ( $I/I_0 = 0.1$ ) with only a  $5^\circ$  black disk in the ERF. Record *h* was obtained under the same conditions, with the exception that three  $3^\circ$  disks were placed peripheral to the  $5^\circ$  central disk—as indicated by the small diagram beside the record. The distance between the centres of the central and peripheral disks was  $7^\circ$ . The general activity has been strongly inhibited. It was possible by placing still more disks in the surroundings to suppress the general activity completely. When a contrast was present only in the area surrounding the ERF, the cell did not fire.

Thus the ERF of class I ganglion cells is surrounded by a concentric inhibitory receptive field (IRF), similar to the spatial receptive field organization of class II ganglion cells<sup>2</sup>. The inhibition extends spatially at least over  $5^\circ$ , thus contradicting Schipperheyn's conclusion<sup>3</sup>. He concluded after using black and white stripe patterns with varying widths that the inhibitory interaction extends only over a distance of about four receptor cells ( $0.34^\circ$ ). The presence of the IRF may explain the observation of Maturana *et al.*<sup>1</sup> that large objects evoked less activity than small objects when moved through the receptive field—it may be that the large objects cause excitation in the IRF as well as the ERF and therefore produce a general reduction of activity.

## Multi-ionic Action Potentials in Molluscan Giant Neurones

IN extension of the "sodium theory" of nerve impulse production<sup>1</sup>, a number of authors have described excitable membranes in which normal inward action currents are carried chiefly by calcium ions in crustacean muscles<sup>2-6</sup> and amphibian heart tissue<sup>7</sup>. It has been suggested that some gastropod giant neurones have "calcium spikes"<sup>8,9</sup>. Oomura *et al.*<sup>8</sup> showed that supra-oesophageal ganglion cells in *Onchidium* continue to produce spikes in media free from sodium or calcium, but become inexcitable if both sodium and calcium ions are removed from the perfusing solution. This behaviour is also seen in *Aplysia* giant neurones and, together with the quantitative effects of varying external ion concentrations, suggests that both sodium and calcium act as carriers of current during the normal action potential.

The experiments were performed on giant "A-cell" somata<sup>10</sup> in the visceral ganglion of *Aplysia californica*. The ganglion was isolated, mounted in a lucite chamber of volume 0.5 ml., and cut open to expose the giant cell to the perfusing solution. Intracellular recording and stimulating electrodes, and the extracellular micropipette used as a reference, were of 3–10 megohms resistance, filled with 2 molar potassium chloride. The normal saline solution contained 494 mmolar sodium chloride; 11 mmolar potassium chloride; 11 mmolar calcium chloride; 19 mmolar magnesium chloride; 30 mmolar magnesium sulphate; and 10 mmolar *tris* hydrochloric acid, pH 7.7.

Test solutions were made by replacing sodium or calcium chloride by an osmotically equivalent amount of sucrose. Before each measurement, the new solution was continuously perfused until 40 times the volume of the chamber had passed through. All experiments were done at 20–23°C.

The effects of varying external sodium while calcium was held constant at three different concentrations are shown in Fig. 1. Some variation of the resting potential was seen after each change of solution, but this was not consistently related to the concentration of sodium chloride. The spike amplitude, measured from the resting potential, varied almost logarithmically with  $[Na]_0$ ; the slope of this relationship was greatest at the least value of the external concentration of calcium,  $[Ca]_0$ , reaching 9.9 mV/ten-fold change in  $[Na]_0$  at  $[Ca]_0 = 11$  mmolar. The maximum rate of rise of the spike varied strongly with external sodium. Surprisingly, the critical depolarization for spike initiation increased abruptly with reduction of  $[Na]_0$ . This increase in threshold may reflect some change in the axonal spike-initiating membrane<sup>11</sup>; the resistance of the somatic membrane, by contrast, was not affected significantly by changing  $[Na]_0$  between 0 and 494 mmolar.

Alteration of the external concentration of calcium while holding  $[Na]_0$  constant at three different values produced the results shown in Fig. 2. Spike amplitude, measured from the resting potential, varied almost logarithmically with  $[Ca]_0$ . As with sodium replacement,

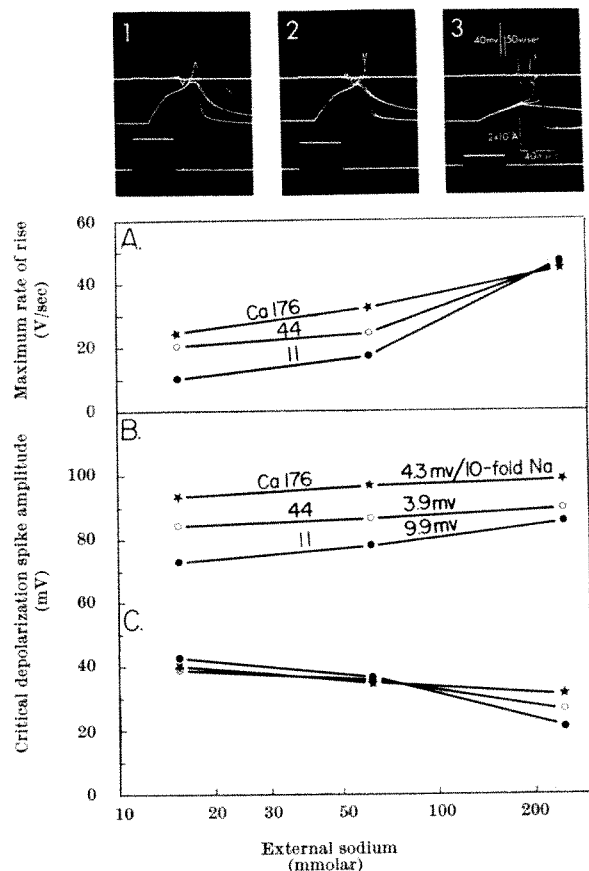

Fig. 1. Effects of partially replacing external sodium with sucrose when  $[Ca]_0$  was held constant. Inserts 1–3: one experiment at  $[Ca]_0 = 11$  mmolar.  $[Na]_0$  was 15.5 mmolar in 1, 62 mmolar in 2, and 248 mmolar in 3. Top trace shows zero potential and rate of rise of spike; middle trace is transmembrane potential, shifted 20 msec to right of top trace; lower trace shows stimulating current, synchronized with top trace. Four sweeps superimposed in each case, to display critical depolarization for spike initiation. Graphs: (A) maximum rate of rise; (B) spike amplitude measured from resting potential; and (C) critical depolarization, as functions of  $[Na]_0$  at three different constant values of  $[Ca]_0$ . Average slopes indicated for the two segments in each curve. Each point is the average of experimental results in three different cells.

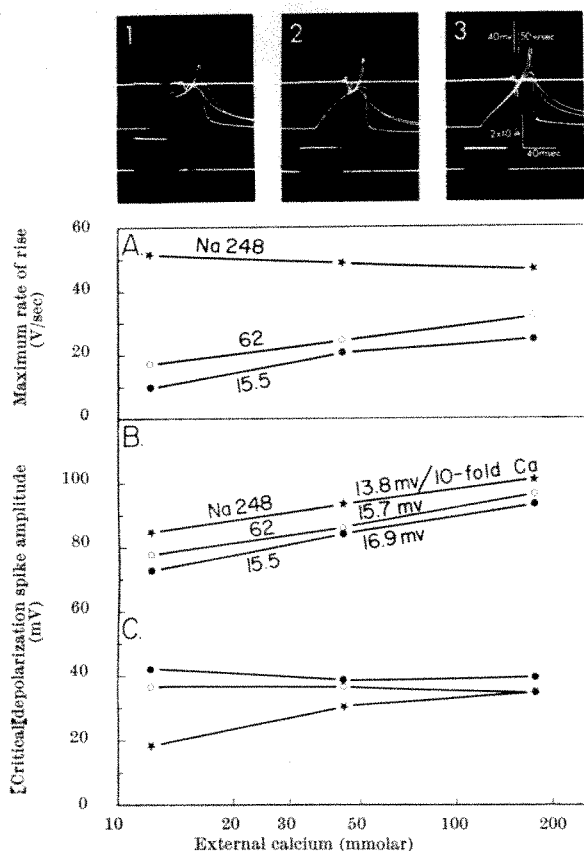

Fig. 2. Effects of increasing external calcium in exchange for sucrose when  $[Na]_0$  was held constant. Inserts 1-3: one experiment at  $[Na]_0 = 15.5$  mmolar.  $[Ca]_0$  was 11 mmolar in 1, 44 mmolar in 2, and 176 mmolar in 3. Top trace, zero and rate of rise; middle trace, transmembrane potential; lower trace, pulse current. Graphs: (A) maximum rate of rise; (B) spike amplitude; (C) critical depolarization, as functions of  $[Ca]_0$  at three different constant values of  $[Na]_0$ . Average slopes indicated; each point is the average of results in three different cells.

the slope of this relationship was greatest at the least concentration of the constant species. The slopes with changing  $[Ca]_0$ , however, were greater in every case than those obtained with changing  $[Na]_0$ , reaching 16.9 mV/tenfold change in  $[Ca]_0$  when  $[Na]_0$  was 15.5 mmolar. These calcium slopes are in the range observed by Gerasimov *et al.*<sup>9</sup> for *Helix* giant neurones. (Note that, as  $[Na]_0$  was increased to more nearly normal values, the spike amplitude showed approximately the same sensitivity to changes in  $[Ca]_0$  as was seen in Fig. 1 to changes in  $[Na]_0$  at the normal concentration of calcium.) The maximum rate of rise was far less sensitive to  $[Ca]_0$  than to  $[Na]_0$  at the more nearly normal concentrations. When plotted, however, for all values of  $[Na]_0$  and  $[Ca]_0$ , the maximum rate of rise was a monotonically increasing

function of the EMF-value (spike amplitude - critical depolarization). This suggested that the maximum rate of rise was determined principally by the size of the rapidly rising part of the spike, and not by the particular ion present in greatest concentration. The critical, or threshold, depolarization was elevated at low values of  $[Na]_0$ , and in that condition was practically independent of  $[Ca]_0$ . Somatic resistance, however, always increased with increasing  $[Ca]_0$ , as was seen by Gerasimov *et al.*<sup>9</sup>. Comparison of a high-sodium ion, low-calcium ion spike (Fig. 1, inset 3) with a low-sodium ion, high-calcium ion spike (Fig. 2, inset 3), indicates that calcium may substitute for sodium, restoring the action potential to normal or greater than normal amplitude, as has been found for neurones in *Onchidium*<sup>8</sup> and *Helix*<sup>9</sup>.

In experiments where sodium was completely replaced by a non-electrolyte, sucrose, it was always possible to obtain all or none action potentials for periods of up to 1 h. In five different cells, the spike height was reduced 12 per cent, 15 per cent, 21 per cent, 30 per cent and 37 per cent on replacing a normal sodium ion medium with a medium lacking sodium ions. The possibility that these spikes could have resulted from a diffusional barrier, preventing the complete removal of sodium ions, was examined by the method shown in Fig. 3. In these solutions free of sodium ions, rapid (1 min) changes from normal calcium to zero calcium caused the cell to become inexcitable, the spike returning with restoration of calcium. Apparently, the action potential in solutions free of sodium ions is largely due to the remaining calcium ions. The converse experiment of removing calcium ions from a normal medium containing sodium ions resulted in a slight reduction in spike amplitude, in agreement with Oomura *et al.*<sup>8</sup>.

To assess further the contribution of sodium to the spike, the puffer-fish poison, tetrodotoxin, was applied in the external solution. This drug blocks the production of spikes dependent on sodium at external concentrations of  $3 \times 10^{-10}$  molar in the frog single node of Ranvier<sup>12</sup>,  $1.5 \times 10^{-8}$  molar in the giant axon of the lobster<sup>13</sup> and  $3 \times 10^{-9}$  molar to  $1.5 \times 10^{-6}$  molar in the squid axon<sup>14</sup> (for further review see ref. 15). The mechanism of action of tetrodotoxin may be a specific occlusion of sodium channels<sup>16</sup>. In my experiments, the addition of tetrodotoxin to the normal saline solution at a concentration of  $3 \times 10^{-6}$  molar did not block the generation of all or none spikes. In four different cells, it caused reductions in spike amplitude of 2 per cent, 3 per cent and 22 per cent after application for about 5 min, and 18 per cent after 30 min. Recovery of spike amplitude was almost complete after removal of the drug. The reduction in spike height caused by  $3 \times 10^{-6}$  molar tetrodotoxin is similar to that obtained here with complete replacement of sodium, and this suggests that tetrodotoxin may act by blocking the sodium ion component of the spike only.

The dependency of spike amplitude on both  $[Na]_0$  and  $[Ca]_0$ , when varied individually, and the persistence of

Fig. 3. Abolition of all or none spikes in sodium free medium by removal of calcium.  $[Ca]_0$  was 11 mmolar in (A), 2.75 in (B), 0.69 in (C), 11 in (D) and returned to 11 in (E). Trace 1, rate of rise and zero level; trace 2, transmembrane potential, shifted to right of trace 1; trace 3, stimulating current pulse. Four sweeps superimposed in each photograph.

the spike in the absence of either cation, are presumptive evidence for a multi-ionic mechanism of carrying action currents. In such a system, the rate of change of action potential size with concentration of calcium, in the presence of a constant amount of sodium, for instance, would be expected to be less than the 29 mV/tenfold change in  $[Ca]_0$  predicted for a calcium electrode. Published data concerning the effect of external calcium on muscle spike heights deviate widely from this simple relationship<sup>6,7</sup>. In each case, it has been possible to explain this discrepancy very well by treating the active membrane as a multi-ionic system.

I thank S. Hagiwara for the research facilities and for his help. This work was supported by a grant from the US Public Health Service.

*Note added in proof.* Another class of molluscan nerve cells has recently been described<sup>17</sup> in which spike amplitude depends on both external sodium and calcium concentrations.

## PATHOLOGY

### Growth of Two Human Tumour Cell Lines in Mice treated with Antilymphocyte Serum

TISSUE culture lines of human tumours can be transplanted into animal hosts conditioned with immunological depressants such as cortisone or irradiation<sup>1</sup>. Several reports<sup>2,3</sup> describe the immunosuppressive action of antilymphocyte serum; mice treated with antilymphocyte serum have a reduced capacity to reject skin homografts. Antilymphocyte serum seems to be the most effective immunosup-

Fig. 1. HeLa cell tumour, day 15. (Haematoxylin and eosin,  $\times 60$ .)

Fig. 2. Hep 2 cell tumour, day 15. (Haematoxylin and eosin,  $\times 945$ .)

pressant yet discovered, and because of its specificity and low toxicity it may provide an improved alternative to methods of host conditioning at present used in tumour transplantation. We have been able to grow two human tumour cell lines in mice treated with antilymphocyte serum.

Antiserum was produced as follows. Thymuses from between six and eight young female *Balb/C* mice were minced in cold normal saline and passed through sterile surgical gauze. The resulting suspension was injected intravenously into New Zealand white rabbits which were given a second injection 14 days later. Serum was obtained 7 days after this, heated to 56°C to destroy complement, and stored at -20°C.

Newly weaned *Balb/C* mice were subcutaneously injected in the ventral midline with a single cell suspension of  $0.5 \times 10^6$  HeLa\* or Hep 2† human tumour cells in 0.1 ml. Eagle's medium, and in the nape of the neck with 0.25 ml. antilymphocyte serum. They were then given a similar injection of antilymphocyte serum three times a week. Control groups were given tumour cells only.

**HeLa cells.** Tumours grew in eleven out of twelve animals given HeLa tumour cells and treated with antilymphocyte serum (Fig. 1). Mice were killed on day 15, by which time most tumours had grown to 5 mm in diameter, and one to 8 mm. Metastases were not found. Tumours did not grow in any of a group of ten control animals. In seven of these animals a small nodule formed subcutaneously, but this had regressed in five animals by day 3, and in all animals by day 10. There was no evidence of tumour growth in any of these animals when examined microscopically.

**Hep 2 cells.** Tumours grew in six out of ten mice given Hep 2 cells and treated with antilymphocyte serum (Fig. 2). In two animals the tumours showed signs of regression by day 13. The remaining four reached a diameter of 4–6 mm by day 15; there were no metastases. No tumour growth was observed in any of the ten animals in the control group.

Secondary transplantation from the growing tumours was attempted. The tumours were minced in normal saline, filtered through sterile gauze, and the resulting suspension subcutaneously injected into mice treated with antilymphocyte serum. No growth was obtained with transplanted Hep 2 tumours. Transplanted HeLa tumours reached a diameter of 5 mm but showed signs of regression by day 12. The mice were killed on day 15. When examined microscopically, the tumours showed a large central area of necrosis not present in the original tumour.

We hope that antilymphocyte serum may prove of value in growing primary explants of human tumour in laboratory animals. We have so far been able to grow one primary explant out of five implanted in mice con-

## Unusual Susceptibility of Lingual Epithelium to Tumour Induction by 4-Nitroquinoline-1-oxide

4-NITROQUINOLINE-1-OXIDE (NQO), a simple bicyclic compound which was synthesized by Ochiai in 1945, is a potent carcinogen. Application of NQO to the skin of mice, rats or hamsters has been shown to induce local tumours<sup>1-5</sup> and also neoplasms of lung<sup>6-8</sup>, stomach<sup>9</sup>, uterus<sup>10</sup> and the lymphatic system<sup>11</sup>. The present report describes the unexpected induction of epithelial tumours of the tongue in mice following the application of NQO and croton oil to the dorsal skin; the doses of these two agents were insufficient to induce more than a few tumours of the treated skin or any neoplasms at other sites. Similar findings have not previously been encountered in this laboratory in numerous experiments in which known carcinogens have been applied to mouse skin.

Two groups of C57 × DBA2 mice were studied, each of thirty female animals which were housed in boxes of six. Mice in Group 1 received 0.2 ml. of 0.2 per cent NQO in acetone applied to the dorsal skin at weekly intervals for 16 weeks; the first dose was given when the animals were 20 weeks old. This was followed by weekly applications of croton oil, initially of 0.3 ml. of a 0.1 per cent solution in acetone. After 12 weeks, the concentration of croton oil was reduced to 0.05 per cent and treatment was continued for a further 53 weeks. Mice in Group 2 acted as controls and were painted with 0.2 ml. acetone alone for the first 16 weeks. Thereafter, they received croton oil for 65 weeks in the same way as the animals in Group 1. Mice in Group 1 died or were killed because of their poor condition, at intervals ranging from 291 to 489 days after the beginning of the experiment. During the same period, only three of the animals in Group 2 had to be killed and the remaining twenty-seven were killed at the end of the experiment, at 563 and 574 days. A full post-mortem examination was carried out on all mice.

The distribution of neoplasms in the two groups is shown in Table 1. The results in Group 1 are of considerable interest: only four skin tumours were produced but neoplasms of the tongue developed in six instances. The animals in which these lesions developed became strikingly cachectic and, in each case, the only abnormality found at post-mortem examination to account for their condition was the lesion in the tongue. Macroscopically, the tumours appeared as ulcerating outgrowths on the dorsum of the tongue. Five of the tumours were squamous

Fig. 1. Tongue from mouse in which NQO and croton oil were applied to the dorsal skin; a keratinizing squamous carcinoma which is widely infiltrating the substance of the tongue. Haematoxylin and eosin × c. 100.

carcinomata and two of these showed extensive invasion throughout the substance of the tongue (Fig. 1). Three tumours were regarded as carcinomata *in situ*; such lesions were confined to the epithelium and the basement membrane was intact but the component cells were grossly disorganized with loss of normal polarity, cellular atypia, and increased mitotic activity. One basal cell tumour was seen. In a seventh mouse, a tumour was diagnosed on gross examination of the tongue but sections at several levels showed only focal hyperplasia of the lingual epithelium with no evidence of malignancy. No metastases from any of these carcinomata were seen and no other lingual tumours, such as sarcomata, were encountered. Apart from one animal which developed an anaplastic lymphoma, no distant tumours were found. Various neoplasms were observed in the control mice but no lingual carcinomata were seen.

These results indicate that an unexpectedly high proportion of C57 × DBA2 female mice develop lingual carcinomata after application of NQO and croton oil to the dorsal skin; this undoubtedly reflects a direct effect on the lingual epithelium of NQO, acquired as a result of licking. Two points are of particular interest. First, the experimental production of tumours of the tongue is apparently difficult. Only two successful reports have been found and, in both of them, the carcinogen was applied directly to the tongue. In one account<sup>12</sup>, 3,4-benzopyrene induced sarcomata (but not carcinomata) in rats. In the other, direct application of NQO in mice was combined with chronic irritation from an implanted metal wire<sup>13</sup>; in the absence of this added mechanical trauma, local painting with NQO produced only one lingual carcinoma. Spontaneous tumours of the tongue in mice have not been observed in this department, nor have such tumours been recorded in the literature. The comparatively large number of lingual carcinomata in the present experiment is therefore most unusual. Second, the increased incidence of these neoplasms is even more impressive when compared with the unexpectedly low yield of tumours of the skin. Unfortunately, it is impossible to assess the degree of exposure of the tongue to NQO but it is improbable that high concentrations of this material remained there for any length of time. This may indicate that, in some circumstances, lingual epithelium is more sensitive to the carcinogenic effects of NQO than the skin. The basis for such a difference in susceptibility is obscure and several factors may be involved. The absence of other tumours commonly induced by NQO such as pul-

Table 1. INCIDENCE OF LINGUAL AND OTHER TUMOURS IN C57 × DBA2 MICE FOLLOWING APPLICATIONS OF NQO AND CROTON OIL TO DORSAL SKIN

Treatment	No. of mice	Skin tumours	Tongue tumours	Other tumours
NQO + croton oil	30	Papilloma Papilloma → carcinoma	2 2	Lymphoma 1
Croton oil only	30	None	Squamous carcinoma 2 Carcinoma <i>in situ</i> 3 Basal cell tumour 1 None	Hepatoma 3 Lymphoma 2 Pulmonary adenoma 1 Carcinoma of breast 1 Carcinoma of ovary 1

monary adenomata suggests that genetic factors may be important; the range of tumours induced by NQO is known to vary in different strains of mice<sup>5,14</sup> and the effects of NQO on *C57 × DBA2* mice do not appear to have been studied previously. Furthermore, local factors in the lingual epithelium itself may predispose to tumour induction. There is evidence, for example, that NQO is mainly active in its reduced form, as 4-hydroxyaminoquinoline-1-oxide<sup>15-17</sup>, and it is possible that conditions in the lingual epithelium favour a conversion of this kind. Conversely, it may be argued that epidermal elements in the dorsal skin of these mice are unusually resistant to the carcinogenic effects of NQO. Some support for this view is provided by recent work by Searle and Spencer<sup>5</sup>, who painted the dorsal skin of *C57Bl* mice with NQO; little epidermal damage was caused but there was a high incidence of local sarcomata. No sarcomata were, however, seen in the present study and it appears that differences in sensitivity to the carcinogenic properties of NQO may occur not only between epithelial and connective tissues but also between two closely similar epithelial surfaces—the squamous epithelium of the skin and the tongue.

### Transplantable Mouse Neoplasm Control by Neutron Capture Therapy

AFTER several years of effort based on the application of the principles of neutron capture therapy, we have empirically evolved a procedure which now can be added to the few effective treatments for established invasive transplantable neoplasms of animals. Previously, we discussed the biological utilization of thermal neutrons to generate alpha particles and lithium atom fragments from boron-10. We noted the pathways of these fragments are of cellular dimensions<sup>1-5</sup>, and how, in principle, one might thereby attain sharply localized intense effects. Our present observations on 611 neoplasms may serve to point towards achievement of these goals. In this communication we report the thermal neutron flux which must be incident on the skin over solid neoplasms 8 mm–17 mm in diameter to result in permanent regression after giving sodium pentaborate intravenously in a dose equivalent to 35 µg/g body weight of boron-10. Only a single treatment was required by this procedure.

Elemental boron enriched to 96 per cent of boron-10 was converted to borax, and then to the more soluble sodium pentaborate. For injections, sufficient glucose was added to the sodium pentaborate solution to attain a molar ratio of glucose : borate of 2 : 1. Glucose has been found to

Fig. 1. Tissue boron concentration changes after prompt intravenous injection in the mouse. Drug, sodium pentaborate decahydrate; dose, 35 µg as boron-10/g body weight. Each point represents an average obtained from ten animals. The analyses of sarcoma were upon homogenates of the dissected neoplasm. □ - - □, Sarcoma implanted in muscle; ● - ●, normal muscle; ○ - ○, blood (mixed).

minimize borate toxicity. Minimum toxicity for sodium tetraborate is attained with a glucose : borate ratio of 1 : 2, but for closely related sodium pentaborate it is 2 : 1 (refs. 6 and 7). The solution for injection was also adjusted to a boron content of 35 µg/0.01 ml. to facilitate administration of the body dose of 35 µg/g from the observed weight. Each solution injected was analysed for boron by the method of Konikowski and Farr<sup>8</sup>. Because excretion of sodium pentaborate by mice has been previously reported<sup>9</sup> as part of the present study, tissue and neoplasm boron concentration were measured on comparable animals at intervals after injection up to 3 h (Fig. 1).

The medical reactor facilities used at Brookhaven National Laboratory have been described elsewhere<sup>10,11</sup>, as has also the field defining aperture unit to hold the mice<sup>12</sup>.

In studies of radiation spectra at the port used, activation of sulphur foils by fast neutrons was negligible. Gold foil activation consistently accounted for nearly all of the neutron flux. Exposure to gamma rays was less than 200 r. for 300 sec exposure. We have previously reported that equivalent neutron exposure without boron-10 has not caused complete regression of the neoplasm<sup>13</sup>, and boron administration by itself was ineffective. The lithium sheet used to line the animal holder in the exposure unit significantly attenuated the thermal neutron flux so that no whole body effects resulted. At each run, radiometric parameters were established by activation of gold foils affixed to the skin over the tumour, at various places on the animal, and about the exposure unit. Counts of the activated gold foils from the skin surface over the tumour indicate the incident thermal neutron flux range in these studies was from  $0.8 \times 10^{12}$  to  $3.2 \times 10^{12}/\text{cm}^2$ .

The neoplasm used was originally obtained in 1951, by intracranial implantation of methylcholanthrene crystals in mice. Subsequently, it has been maintained in young mice by intracranial passage. By use of young mice, not only was intracranial injection made easier, but the incomplete calcification of the skull permitted the enlarging tumour to expand modestly the cranial cavity which permitted a slight, but useful, increment of longevity. Under these conditions a satisfactory passage tumour can be obtained every 8 or 9 days. The details of the procedure used in passage have been reported elsewhere<sup>12</sup>.

When an intracranial passage neoplasm is implanted into the thigh muscle and takes, it grows in a solid mass up to 30 mm diameter (Fig. 2). First passage intramuscular implants about 10 mm in diameter were used to provide sufficient inoculum to develop the number of experimental neoplasms required for each series of reactor runs. The histological cell type, whether of muscle or brain implant, resembles an anaplastic sarcoma (Fig. 3). Maintained in the fashion noted<sup>12</sup> the cell type and invasive quality have remained quite uniform since 1951.

Healthy animals with tumours implanted in the thigh were weighed immediately before injection. The weights ranged from 18 to 24 g. The tail vein was used for injection.

tion. The warmer incorporated into the mouse holding device<sup>13</sup> encouraged dilatation. Unless delivery into the vein was complete and easy within a nominal three seconds, the animal was discarded.

After injection, the animal was positioned in a plastic centrifuge tube (1.377 in. diameter, 4 in. long), while a hole in the bottom allowed the leg bearing the neoplasm to extrude and project. The tube containing the animal was then placed in the exposure holding device; the leg bearing the neoplasm projected into the open central core area of the unit. Approximately 30 min later the neoplasm, together with the entire leg, was bathed in a thermal neutron cloud. The elapsed time between injection and exposure among each battery of 5 animals run at a time range from 30 min after completion of the injection of the first animal to 26 min for the fifth.

After exposure, ranging from 100 to 300 sec, depending on the flux planned, each animal was promptly removed from the holder, the gold foils were collected for counting and the mice returned to their cages. No immediate effects were noted. Subsequently, the animals were observed until their death, which for many was over 2.5 yr later.

Of the 611 animals bearing neoplasms, in 378 (62 per cent) the neoplasm regressed permanently (Table 1). In none of these animals was any mass detectable at the tumour site by one month after treatment. Most of these 378 animals were observed for their remaining life span, approximately 2.5 yr, but a few were killed earlier for histological study. The percentage of permanent regression increased with increasing neutron flux, while increasing the diameter of neoplasms resulted in decreasing per-

centages of permanent regression. These data are completely compatible with observed thermal neutron attenuations in tissue where the half-distance is less than 1.5 c.

Of the 233 (38 per cent) of the animals dying from the neoplasm, in 205 (33 per cent) the tumour was observed to regress for a short, but variable period after treatment.

In only twenty-eight neoplasms (5 per cent) was there no evidence of any regression. In all of the animals with apparent regression, but recurrence, the recurrence was clearly evident by the end of the second month following treatment. Average longevity of an animal with a neoplasm growing at its usual rate was 6-7 weeks.

Leg sections of selected animals with complete regression studied histologically after killing, or after completion of the life span, revealed no evidence of residual neoplasm. The muscle, which had abutted and surrounded the site of the neoplasm, and its vascular structures did not show evidence of damage from either the neoplasm or the treatment (Fig. 4).

Studies are reported on 611 mice bearing a transplantable neoplasm as a thigh implant treated according to the principles of neutron capture therapy. Permanent and total regression for the animal's life span (up to 2.5 yr) was observed in 378 (62 per cent). In 205 animals (33 per cent) transient regression of the neoplasm was observed during the first month after treatment. In twenty-eight animals (5 per cent) there was no evidence of regression.

Data are given to show relation between thermal neutron flux and results upon neoplasms ranging in diameter from 8 mm to 17 mm in stepwise increments of 1 mm. For any given neutron flux, decreasing effects were seen as the neoplasm diameter increased. This is in agreement with expected attenuation of thermal neutron clouds in tissue. The boron-10 dose administered intravenously was 35  $\mu$ g of boron-10/g body weight. It was given 30 min before neutron exposure.

(Tumour diameter on day of treatment—mm)

611 treated neoplasms; 378 (62 per cent) permanently regressed; 205 (33 per cent) temporarily regressed and 28 (5 per cent) no evident regression.

Histological study revealed no neoplastic cells at neoplasm sites after successful treatment. Under the conditions of the experiment, the normal muscle and vascular tissue at the site of the regressed neoplasm appeared unaffected by the treatment.

Longevity of successfully treated animals was not significantly altered from normal expectancy.

### Absorption of Cholera Toxin into Blood from a Separated Jejunal Segment

ONE of the chief problems in cholera research is whether the toxic agents primarily responsible for the diarrhoea are confined to the intestinal tract, or are absorbed into the blood. Finkelstein<sup>1</sup> has suggested that there is only one important toxin, cholera toxin, which produces diarrhoea in infant rabbits, and that this does not leave the intestine, because he has found that cholera toxin injected intravenously does not cause cholera. The question is of practical importance because, if important toxins do not reach the blood, circulating antibodies will have no effect on them, and it has been suggested that prophylaxis should concentrate on an attempt to build up local antibodies in the intestine (sometimes called copro-antibodies), for example, by means of an oral vaccine.

Dutta and Habbu<sup>2</sup> showed that infant rabbits infected intra-intestinally with vibrios, suffered from a disease which very closely resembled human cholera. Furthermore, it was shown that sterile vibrio extracts

Fig. 1. Diagram of operation.

could produce cholera-like diarrhoea in infant rabbits<sup>3</sup>. The background to the present experiments was that one of us, who had had experience of making fistulae and intestinal loops of various kinds<sup>4</sup>, thought that if it were technically feasible to prepare similar intestinal fistulae in infant rabbits, a definite answer might be found to the question as to whether one of the important routes for the distribution of toxin was the blood. We proposed to separate off a segment of jejunum, with one end blind and the other opening to the exterior as a fistula ("Thiry loop") and to restore the continuity of the remainder of the gastrointestinal tract by anastomosis. Vibrios, or their lysate, could then be introduced into the separated segment, which had its blood supply intact, and if the animal later suffered from characteristic cholera-like signs, the toxins must have travelled by the only route available to them, the blood (Fig. 1).

In the event, a hundred and two operations were performed. The first twenty had to be rejected for various reasons (obstruction, leaking anastomosis, and so on), but ultimately thirty operations altogether were completely successful, in the sense that either the animals survived for a long period, or, if they died after infection, no other possible cause of death could be found at post-mortem. The animals were always returned to the mothers after the operations.

In the animals used as controls, 0.2 ml. of sterile medium was introduced into the segment opening on to the skin, either at operation or 24 or 48 h later. In three of them, loose stools were passed for a brief period, but all animals themselves looked perfectly healthy and lively throughout. Only one control died spontaneously, for no obvious

reason (possibly because of dehydration through loss of secretions from the separated segment). The remainder, having lived for longer than the infected animals, were either killed for comparison or used for further investigations (Table 1). The control animals gained weight. At post-mortem the intestines of the killed animals were normal apart from a few adhesions.

In twenty-one animals, rabbit passaged *V. cholerae* Inaba 569B organisms were introduced into the separated segments at operation, or 24 or 48 h later. Fourteen of the infected animals were dead within 48 h of infection (Table 1). Ten of the fourteen had diarrhoea before death and in seven of them the diarrhoea was severe. At post-mortem, a distended caecum and colon, containing clear "rice water" fluid, and flakes of intestinal contents were found in all but one of the animals. Of the seven infected animals which lived more than 48 h, two had diarrhoea. No. 67 was reinfected, 77 h after operation, through the separated segment with  $2 \times 10^5$  vibrios, and later had diarrhoea, but recovered. No. 28 was killed 44 h after infection but was apparently normal.

In the control animal No. 82, 6 days after the operation, 50 mg sonicated toxin<sup>5</sup> of rabbit-passaged Inaba 569B was introduced into the separated segment, but the animal did not develop diarrhoea and lived another four days. In control No. 61, 16 days after the operation, 75 mg toxin was introduced into the separated segment. The animal developed copious diarrhoea, and was dead within 15 h. At post-mortem the distal caecum and the colon were distended with clear rice water, in which flakes of intestinal contents were floating.

Of the seven animals (Nos. 28, 67, 80, 83, 84, 92 and 98) which survived for more than 48 h after infection, two developed diarrhoea, and it was argued that all of them had probably suffered from cholera to some degree. If so, they should have become immunized and resistant to toxin.

In infected animal No. 80 (marked with two asterisks (\*\*)) in Table 1, 11 days after the operation, when it had gained weight to 113 g, 50 mg of toxin was introduced into the separated segment, and it did not develop diarrhoea.

When infected animals Nos. 83, 92 and 98 (marked with a single asterisk (\*) in Table 1), had been alive for 10, 6 and 5 days after operation respectively, three normal rabbits of the same ages were selected, and all six animals were anaesthetized, and 100 mg of sonicated toxin was injected intra-intestinally. After 8 h all the animals were alive. The three normal animals, but not the operated ones, had copious diarrhoea. All six were dead within 15 h. At post-mortem, the caecum and large intestines were enormously dilated with clear rice water fluid and flakes in the normal animals, but were unaffected in the operated animals.

Fluid was taken from the caecum of fourteen infected animals under strictly sterile conditions and cultured. In no case were *V. cholerae* grown, but there was growth of *Escherichia coli* or *Aerobacter aerogenes*, and some unidentified Gram-negative bacteria.

Organisms from the caeca of five animals were cultured on agar for 18 h. A loop-full (1 mm) from this growth was sub-cultured on 10 ml. broth for 3 h, and 1 ml. was then injected intra-intestinally into normal 10 day old rabbits. None showed diarrhoea or any other sign of toxicity. Additional evidence is thus provided that the deaths of the animals infected with *V. cholerae* in the separated segments were due to absorbed toxin, and not to any organisms in the main intestinal tract.

Fluid was also taken from the separated segments of eight animals and cultured. In every case, the fluid grew cultures of *V. cholerae*. We conclude therefore that the most probable explanation for these results is that a toxin of principal importance is absorbed into the blood of infant rabbits from *V. cholerae* in a separated segment of jejunum, and causes characteristic signs of cholera in the whole animal.

In three of the animals which survived infection, evidence was obtained which would be consistent with the view that their intestines had acquired protection against a large dose of sonicated toxin introduced intra-intestinally. The animals died, however, and evidently did not acquire adequate protection against those fractions of the total toxicity of *V. cholerae* which are lethal, but do not produce diarrhoea<sup>6</sup>.

We thank Dr H. I. Jhala for his invitation to E. M. V. W. to study this problem at the Haffkine Institute, and Dr N. K. Dutta for his advice and facilities provided. We also thank Miss Ratna Motwani for the gift of the sonicated toxin of *V. cholerae*.

## PSYCHOLOGY

### Detection of Visual Stimuli located within Angles

THE upper member of two horizontal lines, identical in length, drawn within an inverted V-shaped bracket appears to be somewhat longer than the lower. This figure is one example of many two-dimensional spatial patterns known as "the geometrical illusions". These patterns undergo distortion in such a way as to assume an appearance markedly at variance with their physical form. This particular figure is usually described as the Ponzo illusion, the distortion characterizing it being seen clearly in Fig. 1. The geometrical illusions have provided the topics for a very large number of experimental enquiries. In these, attempts have been made to understand the spatial distortions seen in them, according to features of the structural organization and functional repertoire of the visual projection system. The purpose of the present communication is to initiate consideration of the problem of perceiving visual stimuli seen in the context of illusions, the Ponzo figure being used as a convenient example.

The facility with which visual stimuli can be seen depends on many factors. Most important of these is the size on the retina of the image resulting from a particular stimulus. Visual acuity is usually specified in terms of the threshold of angular resolution of the eye with respect to a given spatial pattern. Accordingly, it is customary to calculate acuity from knowledge of the size of the

Fig. 1. The Ponzo illusion.

Fig. 2. The experimental materials.

Fig. 3. The probabilities of detecting each of the ten stimuli.

stimulus resolved and the distance at which it is placed in relation to an observer. The two horizontal lines of the Ponzo figure, however, are of the same length. Thus they subtend similar angles at the eye and the retinal image resulting from each is of the same size. Nevertheless, the two lines appear to differ appreciably in length. Thus the problem under consideration is whether detection is determined by the real or apparent characteristics of this figure.

The materials used for preparing the experimental stimulus patterns are shown in Fig. 2. Eleven different stimuli were used. In ten of these one of the square blocks was placed within the 60° angular bracket, in the remaining pattern the block was omitted. Prepared as photographic slides, these figures were exposed in a tachistoscope for a period of 1/125 sec to subjects who were asked to indicate whether or not a block was present. In each experimental run forty angles containing blocks and forty angles without blocks were included, the random order in which they were presented being changed on each occasion.

The results of this experiment, completed on a total sample of thirty-three subjects, are shown in graphical form in Fig. 3. They refer to the upper and lower rows of stimuli illustrated in Fig. 2, numbered along the abscissa from left to right, from 1 to 5. The ordinate of the graph refers to the facility with which stimuli were seen in each position. The probability function for detection of the upper row of blocks is plotted in solid line and for the lower row in broken line. The standard error of estimate of each point defining both graph lines is indicated by a vertical solid bar.

It will be readily seen that these two graphs do not describe a common relationship. For each position the probability of detecting a stimulus in the upper row significantly exceeds that of a corresponding stimulus in the lower row. Taken as a whole, detection of stimuli in the upper row, in comparison with the lower, is facilitated by a factor of the order of 10 per cent. This approximates

to the extent of attenuation of the lower line in relation to the upper in this particular version of the Ponzo figure. Accordingly, it appears justifiable to conclude that the apparent features of illusory spatial patterns rather than their actual physical characteristics determine the probability with which near-threshold stimuli can be detected.

## ANIMAL BEHAVIOUR

### Sexual Attractiveness and Receptivity in Rhesus Monkeys

THE catarrhine monkeys and the apes alone among animals have a clearly defined menstruation with a cycle lasting about 30 days. They do not show well-circumscribed periods of oestrus (heat), but will copulate throughout the cycle. This has led to the idea that the great development of neocortical mechanisms in the primate has resulted in an emancipation of its brain from the influence of gonadal steroids<sup>1</sup>. Earlier work in both the rhesus monkey<sup>2,3</sup> and the chimpanzee<sup>4-6</sup>, however, has indicated that the level of sexual interaction shows some variation with the phases of the menstrual cycle. Furthermore, studies of the rhesus monkey<sup>7,8</sup> have shown that well marked rhythms of mounting behaviour by males occur in relation to the menstrual cycles of their female partners. These rhythms are abolished by bilateral ovariectomy, and so endocrine mechanisms in primate sexual behaviour seem to have been underestimated<sup>9</sup>.

Copulation in the rhesus monkey consists of a series of sexual mounts by the male on the female, each with an intromission and thrusting, the series being terminated by a final, ejaculatory mount. The mounting sequence is not haphazard, but results from initiating movements by the male (for example, courtship postures, mounting attempts or claspings), and from initiating movements by the female (sexual presentations and various invitational gestures). Endocrine-dependent changes in the mounting activity of the males could therefore be mediated by changes in this initiating behaviour. This communication attempts to account, in behavioural terms, for the conspicuous decline in male mounting activity that occurs early in the luteal phase of the menstrual cycle.

Mature, intact male and female rhesus monkeys, weighing 8-14 kg, were studied in glass-fronted observation cages for 60 min periods by two observers, in carefully standardized conditions. Between tests animals were housed singly. Four females were used, each was tested with two males for a total of fifteen menstrual cycles involving 176 h of observation, and in eight cycles rhythmic changes in mounting occurred. A system, previously described, was used for scoring components of behaviour at 30 sec intervals giving their temporal sequence<sup>10</sup>. The present report is confined to the way in which the hormonal status of the female influences the outcome of mounting attempts by the male and of sexual invitations by the female.

Fig. 1 shows the changes in each test during four menstrual cycles: (a) in the number of mounts made by the male on the female; (b) in the number of sexual invitations made by the female to the male, and (c) in the proportion of these invitations that stimulate the male to mount. The latter is termed the female success ratio—successful mounting invitations (those followed by a mount) expressed as a percentage of total mounting invitations made by the female. Although rhythmic changes in the number of mounts in a test occurred in relation to the menstrual cycle, with a well marked decline early in the luteal phase, the number of female sexual

invitations remained at about the same level throughout the cycle, and did not decline when male mounting activity did so. The proportion of these invitations that were accepted by the male and resulted in a mount (the female success ratio), however, diminished markedly during the luteal phase when male mounting activity declined. In such cases, type *A*, the decrease in mounting activity was clearly related to the diminished effectiveness of the female sexual invitations, reflecting her diminished value as a sexual stimulus at this time.

This is not, however, the only mechanism responsible for the decline in male sexual activity observed early in the luteal phase. Fig. 2 shows the changes in each test during three further menstrual cycles: (a) in the number of mounts made by the male on the female; (b) in the number of mounting attempts made by the male, and (c) in the proportion of these attempts accepted by the female and followed by a mount. The latter is termed the male success ratio—successful mounting attempts (those followed by a mount) expressed as a percentage of total mounting attempts made by the male. Although the number of mounts declined in the luteal phase of these cycles also, this was not associated with any corresponding decline in the number of male mounting attempts. The

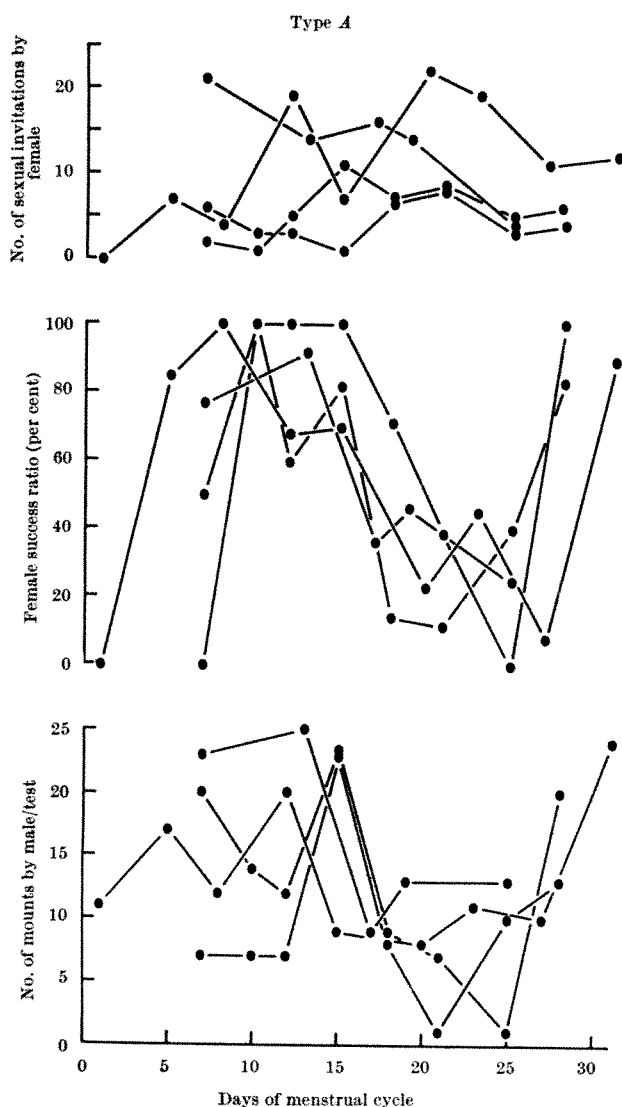

Fig. 1. Although sexual invitations in these females do not decline in the luteal phase of the menstrual cycle, the proportion accepted by the male (female success ratio) does so. This decline in female "attractiveness" correlates with the decline in male mounting (four of five cycles are illustrated).

Fig. 2. Although mounting attempts by the male with these females do not decline in the luteal phase, the proportion resulting in a mount (male success ratio) does so, and the number of mounts declines. This is because of increased refusals by the female (three cycles).

proportion accepted by the female, the male success ratio, however, conspicuously declined when the number of mounts declined, and this was caused by a corresponding increase in the number of active refusals of male mounting attempts made by these females. In these cases, type *B*, the female had not lost her attractiveness, for the male continued to attempt to mount, and a female refusal mechanism was therefore brought into play during the luteal phase.

By analysing primate sexual behaviour in this way, it was possible to differentiate between the sexual "drive" of the female, on the one hand, expressed by the number of sexual invitations, and her value as a stimulus for the male, on the other, expressed by the female success ratio. Two distinct mechanisms thus seemed to underlie the decline in male mounting activity early in the luteal phase: the first depended on a decrease in the attractiveness of the female, indicated by the failure of her sexual invitations to stimulate mounting; the second depended on a decrease in the receptivity of the female, indicated by an increase in the number of female refusals. Further studies of ovariectomized females given oestrogen and progesterone have shown that these mechanisms can be brought into operation in different females by progester-

one; this may account for its inhibitory effect on ejaculation reported elsewhere<sup>11</sup>.

We thank Dr J. Herbert for his assistance and Mr M. Sullivan for his care of the animals. This investigation was supported by grants to R. P. M. from the Medical Research Council, the Bethlem-Maudsley Hospital Research Fund and the National Institute of Mental Health, US Public Health Service.

## GENERAL

### An Early Reference to Genetic Coding

SCHRÖDINGER's little book *What is Life?*<sup>1</sup> is usually thought to contain the first reference to genetic coding<sup>2</sup>. It is therefore surprising to find that Johann Friedrich or "Fritz" Miescher (1844-1895), the discoverer of nucleoprotein and nucleic acid, expressed his belief in the existence of a chemical code within the hereditary material 52 yr before the publication of Schrödinger's discussion on the "hereditary code-script". Miescher's remarks are to be found in two letters which he wrote to his uncle, Professor Wilhelm His, the first in December 1892 and the second in October 1893. They are included in the letters which Miescher's friends collected together and published in 1897 (ref. 3). In the twenty-eight-page biography which Wilhelm His contributed to this volume they are mentioned very briefly in a footnote. We have also found one reference to Miescher's comments on the isomerism of the hereditary material by Jack Schultz in 1941 (ref. 4). The following is an extract from our translation of the first letter.

"To me the key to the problem of sexual reproduction is to be found in the field of stereo-chemistry. The 'gemmules' of Darwin's Pangenesis are no other than the numerous asymmetrical carbon atoms of organic substances. As a result of minute causes and external conditions these carbon atoms suffer positional changes and thus gradually produce structural defects. Sexuality is an arrangement for the correction of these unavoidable stereometric architectural defects in the structure of organized substances. Left-handed coils are corrected by right-handed coils, and the equilibrium restored. In the huge molecules of albumen compounds or in the yet more complicated molecules of haemoglobin, etc., the many asymmetric carbon atoms provide a colossal amount of stereo-isomerism. In them all the wealth and variety of hereditary transmissions can find expression just as all the words and concepts of all languages can find expression in twenty-four to thirty alphabetic letters. It is therefore quite superfluous to make the egg and sperm cell a storehouse of countless chemical substances each of which carries a particular hereditary quality (the Pangenesis of de Vries). My own research has convinced me that the protoplasm and the nucleus, far from consisting of countless chemical substances, contain quite a small number of chemical individuals [compounds] which are likely to be of a most complicated chemical structure."

There is no suggestion of a chemical code in the specific sense of the repetition of varied sequences of a few bases; this is hardly surprising because only two of the four common bases had been isolated from nuclei when this letter was written and there existed no information about their relative proportions until 1902 (ref. 5) (for adenine uracil and guanine) and 1909 (ref. 6) (for all four). Nor does Miescher identify his "chemical individuals" as nucleic acids or nucleoproteins. But the researches to which he refers showed that four-fifths of the sperm head is composed of nucleoprotein, so we may be fairly confident that he had this class of compounds in mind. His choice of proteins as examples of compounds with a high potential for stereoisomerism resulted probably from the fact that more was known about their composition than about that of nucleic acids.

Miescher was possibly the first biochemist to perceive the biological possibilities of Le Bel and van't Hoff's theory of the isomerism of the carbon tetrahedron (1874) and to speculate that stereometric alterations may be the cause of mutations. Remarkable, too, is the fact that this discoverer of nucleic acids was thinking in terms of right- and left-handed threads or coils. This conception of the hereditary material may have been pure speculation, but it could have been based on the knowledge that chromosomes at division show a coiled structure since this fact was clearly demonstrated by Baranetzky in 1880 (ref. 7). Admittedly this is at a very different level, but the analogy was there. Thus while other biologists were still talking about "arrangements" in vague terms, Miescher had arrived at a more sophisticated conception. He complained that men like Weismann "speculate and torment themselves with half-baked concepts which are either ill-defined or belong to an antiquated state of chemistry". The great questions relating to genetic continuity, he forecast, "will have to be fought out between the morphologists and biochemists of the twentieth century. Is it only substance or is it form as such which is inherited? By form I mean internal morphological structure, with well-defined external borders, and I do not care whether or not that structure is at present open to analysis". This quotation comes from a letter which he wrote 3 weeks before his death from consumption in 1895 at the age of fifty-one. It is tempting to speculate on what he would have thought of the erroneous and, to a man of his perceptiveness, naive tetranucleotide theory of nucleic acid structure had he lived to see its birth in 1909 (ref. 6). Well did his Uncle Wilhelm say: "The appreciation of Miescher and his studies will not decrease but increase with time, and the facts he discovered and the ideas he conceived are germs for which a fruitful future is approaching"<sup>8</sup>.

We wish to thank Professor Darlington for advice. This work forms part of a general history of nucleic acids which one of us (R. C. O.) is preparing with support from the Royal Society.

## BOOK REVIEWS

## ENGLISH HIPPOCRATES

Dr Thomas Sydenham (1624-1689)

His Life and Original Writings. By Kenneth Dewhurst. Pp. viii + 191 + 8 plates. (London: The Wellcome Historical Medical Library, 1966.) 35s.

DR DEWHURST has continued his researches into medical biography. He made good use of the Lovelace Collection of John Locke's papers in the Bodleian Library for his admirable life of that physician and philosopher; and now has found them of value, together with other original material, for a study of Sydenham's life and writings. Sydenham called Locke from chemical research to study the natural history of disease at the bedside.

The first part of this book is devoted to the life of Sydenham, and the second part contains the original drafts of his writings which were penned in English. Medical works were expected to be published in Latin in the seventeenth century, and so several persons (identified by Dr Dewhurst) translated them. The translations were not always accurate, and we are now able to appreciate fully the teaching of Sydenham as he set it down in his mother tongue. He wrote some of his later works in Latin; for instance, his *Treatise on Gout and Dropsy*, translated by Dr John Drake into English in 1683, and his *Processus integri*, published posthumously in 1693. The concluding pages of the book contain correspondence including some letters from Sydenham to Locke.

This remarkable man of genius seems to have been born a physician, for he owed little to academic training in medicine, and, indeed, despised it: "Physic," he said, "is not learned by going to universities."

Thomas Sydenham was born at the manor of Wynford Eagle in Dorset. He came of a well-to-do Puritan family. His father, William Sydenham, Thomas himself and his three brothers served in the parliamentary army in the civil war. Two of the brothers were killed, while the eldest brother, William, a staunch adherent of Cromwell, became Governor of Weybridge and the Isle of Wight, and a member of parliament. Much new information is given on Sydenham's early life and war experience.

He was educated at Dorchester Grammar School. In 1643 he entered Magdalen Hall, Oxford, but soon left to become a trooper in the parliamentary cavalry, rising to the rank of captain. After the war he returned to Magdalen Hall in 1647, to migrate a few months later to Wadham College. Being on the winning side he did not undergo the frustrations that Locke afterwards experienced in obtaining the M.B.Oxon. The Earl of Pembroke, the Chancellor, conferred this degree on him in 1648; he was then made a fellow of All Souls' in place of an ejected royalist.

Sydenham resided for a few years at Oxford. He returned to the army for a brief period and was at the Battle of Worcester. Robert Boyle became his friend, but otherwise he seems to have held aloof from the experimental scientists, the precursors of the Royal Society in the University. He never mentions Harvey's discovery of the circulation of the blood. In 1655 he resigned his fellowship to marry Mary Gee. Soon afterwards he settled in practice in King Street, Westminster, removing to Pall Mall in 1664. He was a licentiate of the College of Physicians from 1663 (never a fellow) and

later M.D.Cantab. (1676). Dr Dewhurst considers that he never studied clinical medicine under Professor Barbeyrac at Montpellier as is often stated.

Sydenham's abiding fame as a physician rests on his study of fevers in which he well and truly laid the foundations of epidemiology. He accepted the Hippocratic theory of "humours", but ignored the erroneous beliefs and disputations of many seventeenth century physicians. He went back to Hippocrates, the source of clinical medicine, and investigated the natural history of disease. Studying prevailing fevers at the bedside of his private patients and in the wards of London hospitals, he found that diseases can be identified as clinical entities, that they pursued a regular course, and that their prognosis could be estimated from their characteristic symptoms. He was able to define a number of diseases, for example scarlet fever, measles, smallpox and gout; and described their "constitutions" as due to inexplicable changes within the Earth, climatic, atmospheric and seasonal variations. "The Epidemic Constitution" of any year determined its endemic or stationary fever, and this fever had an effect on any epidemics in that year. He also studied plague in the great plague of London.

Sydenham's treatment of disease was simple and enlightened; it comprised riding in suitable cases, living in the open air, little purgation and bleeding, rest and sleep. He also prescribed opium and other drugs, but mainly relied on the *vis medicatrix Naturae*. Curiously for so careful an observer he did not believe that smallpox was contagious. His "cooling treatment" of that disease under which his patients did well was criticized by the physicians of the day, who alleged that his therapy consisted in doing nothing. But his teaching and fame became world wide.

Thanks to Dr Dewhurst we now know much more about Thomas Sydenham, "the English Hippocrates".

ARTHUR MACNALLY

## WITTGENSTEIN MISCELLANY

## Zettel

By Ludwig Wittgenstein. Edited by G. E. M. Anscombe and G. H. von Wright. Translated by G. E. M. Anscombe. Pp. x + 248. (Oxford: Basil Blackwell, 1967.) 37s. 6d. net.

THE late provost of Queen's College, Oxford (Canon B. H. Streeter), once remarked on the value of having at hand an intellectual workshop, where ideas could be left lying about, and there was no need to tidy them up. When the right moment for assembly arrived, any number of stray thoughts could be brought to life, and thus become significant. Such a collection is sometimes of unique value, even if the author is dead. This is, in outline, the situation before us in the notes left in a box-file by Ludwig Wittgenstein (1889-1951), and now published by his literary executors. In fact, these 717 clippings (or *Zettel*) are fragments of typescripts on which, it seems, the philosopher intended to work at length when the mood occurred and the opportunity offered. Evidently, he considered some of them at least to be capable of extension and possibly of systematization. A portion of the material, however, is largely repetitious: Wittgenstein wrote a vast amount, too, in both these respects a little like Newton. The editors have tried to follow a plan, according to the subject matter. It might have rendered the reader's task a little less difficult if divisions could have been indicated in the text by a horizontal line, or some such device. The whole is simply a bundle of thoughts. Without comment and without criticism—some of them fairly loose and likely to fall out, others tightly bound and most intractable. Nobody could read these pages effectively who did not venerate Wittgenstein,

or understand how fiercely he sought for truth even when, as he himself would have admitted, he was near to writing nonsense.

Supposedly, he intended to elaborate these cogitations into further full-scale studies concerning the meaning of sentences, the theory of signs, the implications of symbolic logic, and especially the methodology of Frege. He shows great respect for Goethe's theory of colour; its metaphysical subjectivity utterly opposed to the mechanics of Newton, and all that followed. This in itself is a manifestation of *Sturm und Drang*; one recollects how Wittgenstein started as an engineer, and even in these jottings speaks almost affectionately of the steam-roller. Again, he likens passing thoughts to the progress of a film-show; an unconscious hark-back perhaps to his habit at Cambridge of making straight for the cinema after his exhausting twice-weekly "supervisions" at Trinity. On these occasions he was probably acting on sentence No. 460—"In certain cases, one cannot take too much care in handling philosophical mistakes, they contain so much truth". This is Wittgenstein at his best, and his most illuminating. Did he realize that in those words he was outlining the whole course of history in relation to the origin and treatment of heresy? In moments crucial for Church or State, it was not the fact that heresy was "wrong" that mattered so much as the nearly universal agreement that its very activity left the residual belief the stronger for its interventions. And thus, the infinite care lavished by Wittgenstein on philosophical mistakes.

This sentence is preceded by two observations regarding metaphysics; the first is that this subject cancels out the distinction between factual and conceptual investigations, whereas the second (pointing to the same basic effect) notes that, according to age-long metaphor, one cannot step into the same river twice. The Wisdom literature, of course, made the same point about birds and arrows in their flight through air. The importance of these entries lies in their refutation of the idea that Wittgenstein abhorred metaphysics. As a former disciple of the Vienna Circle this might have been so (a book is in preparation about this topic), but in his later work he seems to have extended almost a welcome to the blurring of the line between fact and concept. Centuries ago, St. Anselm came to grief just here, with his ontological argument for the existence of God.

Again and again Wittgenstein, aided perhaps by his passion for condensation, sees the difficulty exactly of making a clean sweep in the metaphysical sense, when at the same time he knows perfectly well that some system of mechanics (not necessarily classical) is, as it were, looking over his shoulder. Here writes the man who once upon a time delighted in the details of aeroplane construction, and when driven too hard by his semantics turned back again to screws and bolts. It would be asking too much to explain exactly why he did this: one guesses that brute fact had retained the same place in his mind as it had occupied in the days of the *Tractatus*. But this is only once more to accept the strong *a priori* element in his fundamental approach to the world, namely, that nobody is likely to understand his thoughts as he jots them down unless the "other mind" (in effect, the *alter ego* of Husserl's phenomenology) had indeed experienced them before.

In sentence No. 613 Wittgenstein discusses the starting and finishing point of a system, noting the exclusion of the intermediate states. This is clearly what usually happens in classical thermodynamics wherein *a* and *b* are states independent of the path. In this language-game sentence Wittgenstein absorbs most of the limitations to which traditional heat theory is prone, but this is not the case, methodologically, with Carathéodory's adiabatic surfaces between which exists total impassability.

The object of reading Wittgenstein in this way is to show how far-reaching his thought is. No physicist is likely to consult him on purely technical grounds, but

ever since the days of Leonardo da Vinci—at least—there has been a veneration for natural law, and incidentally for the use of the subjunctive. Maybe this is it, but if so, it accords ill with modern efforts to display structure rather than to rest content with something "independent of a mechanism".

When we consider, as we are told, that these meditations represent Wittgenstein's thoughts during 1929–48 (but mostly the last three years of that period), a natural question to ask is whence came such an avalanche of creative strife? Looking back at the Vienna of Wittgenstein's youth and formative years, the atmosphere must have been quite extraordinary—Johannes Brahms a friend of the family, Mach, Boltzmann, Schlick, Gödel, a galaxy of talent if ever there was one. Yet Wittgenstein was to know several suicides and one murder, even in his own relatively small circle. I suspect that the language-game which he played all his life arose in part as a counterweight at once challenging and grievous. And the lengthy references to the nature and influence of pain are long-range reflexions of so deep a tension.

The editors have succeeded in keeping some of the best until last. The thoughts on the propositional calculus and the antimonies begin at No. 681 and continue almost up to the end. Additionally, there is the warning remark to the effect that it is stupid to embark on the investigation of an infinite regress: there is no goal, and therefore no sense in setting out to reach it. In this context, however, one should perhaps bear in mind the possibility of an escape clause such as that in some "comparative" philosophy like the second "way" of St. Thomas Aquinas. Whether it is legitimate to see in this (as the late Sir Edmund Whittaker did) a "proof" of the existence of God, conceivably compatible with modern physics, is another matter. The point is that in cases wherein "greater than" or "less than" occurs, the end-point is not necessarily excluded from the start. A mathematical question (No. 697) is seen as a stimulus to imagination: in the next note a parallel is drawn with the act of translation from one language into another, and the great difficulty of doing so, if judged as a matter of replacement. Wittgenstein seizes on the essential element, namely, the absence of a systematic method of solution in both cases. History shows clearly enough that great advances are often made by inspired guesses, whereas "system" followed later, in much the same way that technical routine follows in the wake of original discovery in natural science.

The reader who can feel his way through this collection of ruminations will reap his reward and proffer his thanks to the editors. As a by-product he will be able to test his grasp of German idiom as he goes along, and noting, *en route*, the four-dimensional cube displayed on the jacket and illustrated in colour in the text.

Wittgenstein is full of surprises, even to his last remark (No. 717)—"You cannot hear God speak to someone else, you can hear him only if you are being addressed".

F. I. G. RAWLINS

## RADIATION PHYSICS IN MEDICINE

### Radiological Physics

By M. E. J. Young. Second edition. Pp. xii + 601. (London: H. K. Lewis and Co., Ltd., 1967.) 84s. net.

THE first edition of this book, which appeared in 1957, was welcomed as filling a need for a textbook covering those aspects of radiation physics which should be understood by medical practitioners specializing in radio-diagnosis or radiotherapy. This new edition attempts to bring the subject up to date, which is no mean task in a rapidly developing field. There is, naturally, much new material, but also some of the earlier work has been

rewritten or rearranged. The result is most successful and the author is to be congratulated on the considerable improvement achieved.

The chapters relating to radiotherapy, perhaps the most authoritative, now cover the more recent developments in high energy techniques. It is disappointing, however, that the chapter on radiodiagnostic procedures, while giving some space to recent developments in image intensifier and television techniques, has no mention of what is perhaps the most significant of recent advances, the application to this field of the principles of information theory. An elementary account of this, together with its implication of quantum limitations in the X-ray image, should surely have been included. In the chapter on the diagnostic use of artificial radioactive materials, the author has wisely elected to discuss a few established procedures rather than to catalogue the many possible applications. Some reference might well have been included, however, to clinical uses of whole body counting; this technique receives only a brief mention in relation to personnel monitoring.

There is a carefully revised chapter on chemical and biological effects of ionizing radiations. From the student's point of view, the chapter on radiological protection would have benefited from more specific detail, for example on the methods of calibrating and interpreting film badges; and it might have been stressed that the data on maximum permissible burdens relate to maintained levels. The selection of examination questions and the references following each chapter have been brought as up to date as publishing time permits.

The book has commendable clarity and the care which seems to have been devoted to its style of expression makes such a lapse as "increasing quality" of radiation all the more remarkable. There is a tendency to over-punctuation, particularly in the insistence on a period after every unit abbreviation. Among errors and misprints noticed is the rather curious substitution of ytterbium for yttrium on page 166 and on page 466 it is implied that the  $k$  factor is identical with the specific gamma ray constant, rather than a particular value of it. Presumably Fig. 11.43 refers to energy absorption in "average soft tissue elements" within bone, but the caption does not say so; in consequence a student might well be puzzled at the apparent discrepancy with Fig. 7.03. The text would have helped to avoid this confusion had it cross-referred to the earlier Section 11.14 on "dose absorbed in soft tissue elements in bone". Such oversights are considerably fewer than in the earlier edition, although the new book is more than half as long again.

This textbook can be warmly recommended to doctors preparing for their professional examinations in radiotherapy and radiodiagnosis and to new recruits in the field of medical physics.

G. W. REED

## IONIZATION AGAINST MAN

### Health Physics

Principles of Radiation Protection. By D. J. Rees. Pp. x + 242. (London: Butterworth and Co. (Publishers), Ltd., 1967.) 70s.

AN increasing number of persons is now employed in duties concerned with protection against ionizing radiations. They range from graduates, mainly in physics and chemistry, to technicians or, indeed, industrial workers engaged in the day to day control of radioactive contamination and other aspects of radiation protection where considerable amounts of radioactive materials are manipulated. In addition, other groups of persons, such as teachers, administrators and public health officials, now require a knowledge of the principles of protection against ionizing radiations. There is thus an increasing need for education and training in the principles and tech-

nology of health physics. It is also noteworthy that there is a conspicuous lack of appropriate textbooks in this field and the present volume is therefore very much to be welcomed.

This book is intended to provide a reasonable level of technical training for persons with no previous knowledge of the subject and with limited basic training in physics, chemistry, biology and mathematics. The book admirably achieves this objective and provides a clear and concise introduction to the subject. Starting with some basic physics such as the structure of matter, radioactivity and the interaction of ionizing radiations with matter, we are led on to a discussion of radiation dosimetry, the biological effects of radiation, standards of protection against radiation arising both internally and externally, the design of radioisotope laboratories and radiation protection measurements. There are many diagrams, some taken from specialized physics textbooks but others constructed especially by the author, and these contribute considerably to the value of the book in teaching and training.

Extensive reference is made to the recommendations of the International Commission on Radiological Protection, but it is unfortunate that the only reference to Publication 6 (1964) is in a postscript and no reference is made to Publication 9 (1966) which offers valuable flexibility in the method of compliance with the maximum permissible doses established by the Commission.

The chapter on biological effects of ionizing radiation provides an introduction to the structure of cells and cell division and devotes several pages to a discussion of the genetic effects of ionizing radiation. Somatic effects, however, are dealt with only briefly and attention is given mainly to the acute effects of whole body irradiation. The only reference to cancer is to induction of cancer of the skin after protracted exposures to high dose rates. There is no mention of the possible induction of cancer from significant amounts of radioactive nuclides lodged in the body, such as radium in the skeleton or radon decay products deposited in the lung, or of the induction of leukaemia from substantial whole body irradiation. The risks of the occurrence of these effects have been reviewed in a report of a Task Group to the International Commission on Radiological Protection, published in February 1966, and also in the reports of the United Nations Scientific Committee on the Effects of Atomic Radiation. Although the doses received, within the permissible limits for workers with ionizing radiations, are so low that the risk of these long-term effects is negligible, it is important that they should be recognized in any discussion of the biological effects of ionizing radiation.

The book contains a very extensive appendix on "Data useful for radiation protection problems". This is an admirable collection of data reproduced from a number of sources. This collection of information, however, is rather badly organized. There are examples of repetition of material; for example, beta particle ranges, beta absorption data, mass absorption coefficients, biological response and standards for radiochemical laboratories are each dealt with in more than one place, often with different figures, in the collected material, apparently as a result of quotation from a number of sources. There is no list of contents to this part of the book. Moreover, many of the data do not quote the original source of publication. (This is partly the fault of the International Atomic Energy Agency, from which some of the data are derived.) The individual graphs and data, however, are useful and must be considered as part of the stock in trade of any operational health physicist. Despite its shortcomings, this is a valuable volume, providing an introduction to the subject and some measure of basic training in health physics as well as being a useful volume of reference for the practising health physicist.

W. G. MARLEY

## STIMULUS IN SOIL SCIENCE

### Soil Chemistry and Fertility

Edited by G. V. Jacks. (Transactions of the Meeting of Commissions II and IV of the International Society of Soil Science, Aberdeen, September, 1966.) Pp. vii + 415. (Amsterdam: International Society of Soil Science, c/o Royal Tropical Institute, 1967.) n.p.

THIS book, which deserves only praise, contains a good sample of current work and thought for those interested in the chemistry and fertility of soils. The forty-three contributions, forty of which are in English, are in six main sections: soil organic matter; major nutrients—split into non-metals and metals; trace elements; nutrient diffusion and flow in soils; and the principles of experimentation in soil-crop studies. Each section is introduced with a review-type paper, but most of the other contributions are based on the results of recent research. An appendix contains a brief account of the soils of Scotland.

The dividend from basic research on topics of agricultural relevance is believed to be among the highest paid by any research activity, mainly because a measure of real understanding can go such a long way. Those who are biologically minded might like to ponder on just one point quoted from page 137. "Because the N : S ratio of soil organic matter is substantially less than that of plant protein, it appears likely that any crop that depends entirely on nitrogen from soil organic matter will obtain an adequate supply of sulphur from the decomposition of organic matter". Clearly, this statement should spark off a chain of thought; for example, "it does not necessarily mean that soils receiving fertilizer N should have fertilizer S because there are natural sources of S, other than organic matter . . . however, when large quantities of fertilizer N are added or when legumes are being grown, the S supply should be carefully evaluated to ensure a proper balance of N and S for plant protein production". Acute sulphur deficiency in crops is, in fact, not all that widespread, but how often is plant protein production quietly limited by supplies of sulphur?

The Aberdeen meeting fulfilled its function by providing a stimulus to research and by permitting specialists to broaden their interests; the book can do the same. Much credit is due to the secretary of the organizing committee, Dr. J. Tinsley, to the editor, Mr. G. V. Jacks, and, not least, to the contributors from many parts of the world who must have submitted manuscripts promptly; the Aberdeen University Press also did a first-class job. In all, a most worthwhile effort under the auspices of the International Society of Soil Science.

P. W. ARNOLD

## BOOK OF PALMS

### The Natural History of Palms

By E. J. H. Corner. (The World Naturalist.) Pp. 393 + 24 plates. (London: Weidenfeld and Nicolson, 1966.) 105s.

A FIRST-RATE account of the palms should be expected from a man of Professor Corner's reputation and long experience in the tropics. The palms are reputed to be second only to the grasses in economic importance and, as Corner rightly points out, they are a family which has been badly neglected. Most unhappily, this book falls short of expectations. In a sense, the author, commenting on Seemann's *Popular History of Palms* (1856), provides a pithy review of his own work when he writes: "It is good reading just so far as one does not go to the original sources".

*The Natural History of Palms* is not faithful to many of its written sources nor to many of the palms themselves. Errors of fact, lack of attention to detail, unqualified

and often contradicted generalizations, inconsistency and a florid style, perhaps designed for but misleading to the lay reader and repugnant to the professional, mar the book. It does, however, draw attention to these remarkable plants, dispels any concept that the coconut is representative of the palms in all their diversity, and focuses attention on the many questions yet to be answered before we understand the palms. Written with obvious enthusiasm, it is regrettable that it was not also written with greater care.

Fifteen chapters devoted to general topics, morphology, geography, evolution, generic notes and classification are followed by two appendices, a glossary, chapter references, bibliography and index. The typography is pleasing, the dust-jacket and halftone plates are handsome, but the line figures, particularly those of habit, inflorescences, and flowers, are sometimes "impressionistic" rather than faithful to detail.

It is possible to comment on only a few of the marginal notes in my copy of the book. *The Natural History of Palms* includes the startling statement on the first page that "A fan palm has been reported from the Triassic of Colorado . . ." It is not documented in the references for the first chapter, but I infer from reference 255 to the tenth chapter that Corner refers to *Sanmiguelia lewisii* which Brown very carefully described only as "palmlike" or "tentatively regarded as a primitive palm" and nowhere as a fan palm. The reconstruction and photographs of the actual impressions do not lend credence to the idea of a fan palm on the model of living palms.

In the same chapter appears this generalization: "The floral parts of the monocotyledon are arranged in threes, not fours, fives, or some higher number as in dicotyledons." Then are the Araceae, Cyclanthaceae, Pandanaceae, some palms, *Paris*, among others with floral parts not in threes, also not monocotyledons? The palm flower is said to have " . . . eventually three sepals, three petals, six stamens, and an ovary with three carpels or three cavities . . ." but " . . . this finality has been experimented with in many different lines of palm evolution from a greater number of stamens and carpels. . . ." The more numerous sepals and petals of *Phytelephas* suggest that the perianth might also have been included with stamens and carpels in the last.

Corner's peculiar style also appears in the first chapter where, considering the growth of the monocotyledonous leaf, he writes: "The bigger the leaf, as in palms, pandans and bananas, the more conspicuous the thrust [of the young leaf upwards by means of basal growth]; in palms it is pre-eminent and it is the key to understanding what is going on in their heads". On page 151 he writes: "The ovary of *Phytelephas* is syncarpous. It consists, that is, not of separate carpels but of an ovary-box or carpellary tube, on which the primordia of the separate carpels are raised on a style to form its five to ten branches or stigmata; into the box the ovules have been transferred. How this is done is not known; . . ." Surely the answer must be "It is not done!"

Professor Corner has missed a splendid opportunity to elucidate the nature of the palm inflorescence. Worse, he dwells at length on the significance of the bipinnate leaf of *Caryota*, yet has incorrectly figured and described the terminus of its main axis which is normally a pair of leaflets rather than a single leaflet as on the lateral axes.

"The flower is the meanest bud that can be made" introduces the chapter on the flower. Meanest does not seem an apt adjective for the female flower of *Lodoicea* stated on page 137 to be " . . . one of the most massive flowers of all. . . ." The diversity of floral morphology among the genera of palms is only partly brought out and there are some strange lapses as: "The exceptional subfamilies without multistaminate flowers are those of *Nipa* [sic], *Phoenix*, and the Coryphoid palms; yet the

Coryphoid *Thrinax* is said to have six to twelve stamens". *Thrinax*, when limited in concept, usually has flowers with six stamens, but the segregate genera *Coccothrinax* and *Zombia* usually have more than six stamens as an examination of descriptions or specimens will definitely show. The author does raise provocative questions about the androecium which are not yet definitively answered.

Three chapters on generic notes deal with selected genera but without any explanation of the basis for selection. Professor Corner disclaims in his preface any intent to provide a book which is systematic or taxonomic. It is regrettable, however, that he did not take some stand on the genera allied (or some of them, at least) to *Cocos* which in the unreliable Appendix B is listed as monotypic, for he gives the impression of a larger genus. This ambivalence is not comforting to the reader. The chapters do not contain useful comparative descriptions but instead comprise a series of miscellaneous jottings including paragraphs on how to climb palms. They, with the sketchy and not always correct characterizations of the family and sub-families in a chapter on classification, as well as careless keys in the fifteenth chapter and Appendix A, might well have been omitted.

Appendix A consists of keys to the "commoner" fan palms and pinnate-leaved palms. What a "commoner" palm might be is nowhere stated. The keys serve best as examples of what to avoid: for example, the couplet (7, page 352) "tropical" versus "temperate" to separate the American *Acoelorrhapha* from *Chamaerops* and *Trachycarpus* in the Old World. The last two are distinguished from each other in the succeeding couplet by "leaf-stalk strongly spiny" versus "slightly spiny". *Chamaerops*, however, is more readily distinguished by the orientation of the longer marginal teeth on the petiole in the vegetative state. *Chamaedorea elatior*, sometimes cultivated, keys to *Desmoncus* in the couplet "climbing" versus "not climbing" (6, page 354). *Euterpe precatoria*, one of the most abundant and widespread American palms, keys to the Old World genus *Rhopaloblaste* because of its pendulous pinnae. Perhaps the flowers (and fruits) which provide characteristics leading to accurate identification are not so mean after all.

Where Professor Corner has worked from first-hand observation, as in his description of the development and fall of leaves in *Actinorhynchus calapparia* (page 43), he has made a distinct contribution. I can only agree with him when he writes that "Palms must be studied in their immensity in nature. They cannot be deduced in a metropolis. . . . The hugeness of palms restores the lesson, so easily forgotten, that biological classification deals not with figment but with living things which were before man". Perhaps it is not only the hugeness of the plants but of the scope and complexity of detail to be considered that has defeated a bold and at least thought-provoking attempt to reduce the essential nature of palms to words.

HAROLD E. MOORE, JUN.

## FUNGI WITHOUT WALLS

### The Cellular Slime Molds

By John Tyler Bonner. Second edition, revised and augmented. Pp. x+205. (Princeton, N.J.: Princeton University Press; London: Oxford University Press, 1967.) 60s.

THE description of this second edition as a revised and augmented version of the first edition needs some amplification, particularly because my review of the first edition was somewhat severe (*Nature*, 184, 1976; 1959). In the eight years since the first edition a substantial amount of pertinent and detailed experimental investigation has been carried out on the Acrasiales. The number of refer-

ences cited in the first edition (up to 1959) was 124, and this included the older descriptive work from 1902 onwards as well as the newer experimental work starting with Raper about 1936. This second edition contains 341 references; a marked increase in a relatively short period, and one which reflects a considerable increase in interest in the group.

Dr Bonner gives his prime interest in writing the book as its usefulness for future experimental research. This edition should help considerably in that direction, for it reviews all the published work that is significant and relevant. Dr Bonner has probably had to compromise between comprehensiveness and reasonable size, but he includes the implications of the different approaches that have been made. These include cell biology, biochemistry, fine structure, physiology, developmental studies and taxonomy. In some connexions the discussion is tantalizingly short. For example, more could easily have been written about the control of orientation in the growth of the sorocarp away from the substratum, but within the space he has used for the book Dr Bonner has hit a good balance between the various aspects. Interest is stimulated, and references to the original work are given and can be followed up.

More than half of the book has been completely rewritten for this edition. The first two chapters, which present a perspective of the Mycetozoa one group with another, and describe the better known members of the Acrasiales, are little changed. There is some additional material where necessary, as in the inclusion of the Proto-steliales, and in the fuller description of the species of *Dictyostelium*. The remaining two chapters of the first edition have been expanded to three chapters, and follow the logic which the author has elsewhere established, by separately discussing the three phases of development, which are growth, morphogenetic movement, and differentiation. As he has stated before, these three phases are very clearly demarcated in the Acrasiales, and this is one of their advantages as material for the study of development, permitting individual and separate analyses of each phase.

The short chapter on growth includes some useful detail on laboratory methods, although I feel that it would have been helpful to have given more in a book with the stated aim of this one. A description of methods of isolation and some discussion of the natural history of the organisms (the outstanding omission of the book) would have been particularly appropriate. I wonder also whether some suggestions for class experiments with *Dictyostelium* might not have been worth while. The organisms are fascinating for this purpose and an introduction to them at an early stage might serve to recruit more contributors to future research.

The remaining two chapters comprise the best of the book. A good deal of the work that has been done with these organisms still does not allow of very firm conclusions, and may be interpreted in more than one way. The author seems to me to be very fair in his discussion and evaluation of the evidence. He is also generous in his consideration of the contributions of the different workers in the field. Where work is inconclusive he points this out, and points the way, often with reasonable suggestions, in which research might be directed. One of the attractive features of this book is the way in which research problems and points of uncertainty are given special attention. I found this part a great improvement on the corresponding part in the first edition. The quality of photographic reproduction is poor; much worse than in the first edition.

While the book is rather short, particularly in view of its price, I think the author, in maintaining the interest at a high level and in permitting the several aspects of research to be seen in proximity and in perspective, has produced a book which should fulfil his aim. More than ever, I find these creatures of absorbing interest.

DAVID PARK

## CLIMATES FOR RESEARCH

### Scientists in Organizations

Productive Climates for Research and Development. By Donald C. Pelz and Frank M. Andrews. Pp. xii+318. (New York and London: John Wiley and Sons, Inc., 1966.) 80s.

THIS is the work of two American social psychologists and it deals with the factors which are favourable to progress in original scientific research when the work is done both by individuals and teams. Observations and opinions of the work of more than 1,300 scientists in university, industrial and government laboratories in the United States were obtained. The numbers of scientists considered were large enough for a proper statistical analysis of the results. The authors claim that the book is based on more extensive objective and quantitative data than has ever before been examined in this area. The study is particularly useful in that the crucial laboratory factors can be modified to some extent by the heads of research departments, managers, and the scientists and technicians themselves. There can be no doubt that much of this investigation is valid for work in British scientific research institutions, but there are differences. The great difference in esteem between the Master's postgraduate degree and the PhD which is held in America does not obtain to the same extent in Britain. The deeper purse which finances many investigations in the United States and the generous staffing which is conducive to adequate teamwork with a well-spread set of complementary specialisms, common in America, are rarer and ideal in Britain. Reasonable financial rewards will operate as a stimulus both to the individual as a person and to the team as an organization which often requires highly sophisticated and expensive apparatus, which on occasion will try the resources of heavy engineering. Research, even in subjects other than physics, has moved far from Rutherford's "tobacco-tin stage".

The authors have portrayed their findings with many charts and tables, and have provided a complete description of the research on which the findings are based. This, in itself, is useful as a model and guide for other workers in sociological fields, who at times have used statistical formulae with little background knowledge of experimental techniques and the interpretation of results. It should be kept in mind that all the statistical analysis in the world may be helpless if the very rare Newton, Planck or Rutherford is caught in their net!

The chief areas which were explored by the authors of the book were freedom, communication, motivations, satisfactions, creativity, age, groups and co-ordination. The principal factors of the results of the researches show that effective scientists were self-directed by their own ideas and valued freedom. But at the same time they allowed several other people a voice in shaping their directions; they interacted vigorously with colleagues. Effective scientists did not limit their activities either to the world of "pure science" or of "applied science" but maintained an interest in both. Their work was diversified. Effective scientists were not fully in agreement with their organization in terms of their interests; what they personally enjoyed did not necessarily help them to advance in the structure. Effective scientists tended to be motivated by the same kinds of thing as their colleagues. At the same time, however, they differed from their colleagues in the styles and strategies with which they approached their work.

In effective older groups, the members interacted vigorously and preferred each other as collaborators; yet they held each other at an emotional distance and felt free to disagree on technical strategies. Thus, in numerous ways, the scientists and engineers who were studied did effective work in conditions which were not completely comfortable, but contained "creative tensions" among forces pulling in different directions.

Among the interesting by-products of the research, which appeared when it seemed important to remove the effects of certain extraneous factors, was the fact that PhDs in government research in America published 50 per cent more than university PhDs, and assistant scientists in government research published twice as much as those in industry. This appeared to stem from the obligations of government laboratories to let the public know where their money was going. Again, the relatively low publication rate among scientists in industrial laboratories could be attributed to "company security".

W. L. SUMNER

## OBITUARIES

### Professor H. N. Green

HARRY NORMAN GREEN, who died on May 16 at the age of 64, published many papers on nutrition, traumatic shock and the immunological aspects of cancer.

He graduated MB, ChB from the University of Sheffield in 1924 and the next year gained his BSc, with first class honours. His MSc and MD followed in 1926 and 1927. He then combined the posts of clinical assistant to Sir Edward Mellanby at the Royal Infirmary, Sheffield, with that of research assistant in the department of pharmacology. After two years as lecturer in pathology at Cambridge, he returned in 1935 to Sheffield as professor of pathology. In 1953 he became director of cancer research at the Universities of Leeds and Sheffield and professor of experimental pathology and cancer research at the University of Leeds.

Green was interested in that part of experimental pathology which has a bearing on clinical medicine. His earlier work, in collaboration with Sir Edward Mellanby, concerned the effects of vitamin A deficiency in the spread of infection. The advent of the sulphonamides as clinically effective antibacterial agents led him to study their mode of action. He demonstrated that bacteria produced one, or possibly more, factors capable of inhibiting the action of the drug. He made considerable progress towards the characterization of these factors.

The advent of the Second World War produced an immediate interest in traumatic shock; Green was approached by the Medical Research Council to investigate the problem. On the basis of conclusions drawn from the clinical examination of cases of industrial injury, he and his collaborators began to examine the problem experimentally. It was shown that adenosine triphosphate and related nucleotides accounted for the shock inducing properties of muscle extracts. A period as leader of British Shock Team 2, Royal Army Medical Corps, enabled him to demonstrate the release of nucleotides from the injured tissues of battle casualties and thus to confirm in man the experimental findings. The background to this work was described in a monograph with Dr H. B. Stoner, entitled *Biological Actions of the Adenine Nucleotides*.

Green's interest in cancer started with a series of investigations on the carcinogen, 2-acetylaminofluorene. These were followed by the study of those fractions of coal tar which were able to inhibit the growth of transplanted tumours in animals, work which was never published in full because of the fear of raising false hopes of an impending cure for cancer. A number of chemically pure tumour inhibiting but non-carcinogenic compounds were isolated and were also shown to be without effect on induced or "spontaneous" tumours in rodents. It was the consideration of this work which led, in 1954, to the immunological theory of cancer. The idea that immuno-

logical mechanisms might be responsible for the integrity and balance of the many different tissues of the body and that cancer might be the expression of a failure of these mechanisms was, at the time it was published, revolutionary and was one of the milestones leading to the resurgence of interest in immunology applied to cancer. The explosive growth of interest in cancer immunology led Green and his colleagues to prepare a text on an immunological approach to cancer which is due for publication within a few months.

Green's great strength was his ability to join together facts and concepts from apparently unrelated fields and thereby to add to the understanding of the subject in which he was interested. He took great pride in the activities of his son and daughter and of his wife, whose increasing reputation as a painter delighted him.

D. B. CLAYSON

### Friedrich Frans Koczy

Fritz Koczy, who died on April 18, was born in Vienna in 1914. He studied mathematics and physics at the University of Vienna during 1934-38; in 1936-38 he worked on his PhD thesis at the Institute for Radium Research under the direction of Dr Berta Karlik. At that time this institute was one of the leading centres for the study of natural radioactivity; its exciting scientific and intellectual atmosphere made a lasting impression on Koczy. His research was directed towards testing a hypothesis of Otto Hahn, that the coloration observed in certain samples of rocksalt was caused by the presence of RaD-F-G—these salts supposedly deposited from radioactive waters emanating from thermal springs. Koczy measured the helium contents of blue and white rocksalts, found no significant differences and disproved the hypothesis. In 1939, at the invitation of Hans Pettersson, the noted Swedish oceanographer, Koczy left Nazi occupied Austria to become a research fellow and to assist in establishing the Oceanographic Institute at Göteborg, Sweden. His chief interest was the application of radioactive methods to oceanographic problems. In particular, he was interested in the distribution of uranium and thorium and their decay products in the oceans, the sediments, and on the continents. On the basis of his measurements of lead isotopic ratios, Koczy calculated the age of the Earth to be 5.3 billion years. This value disagreed considerably with the favoured estimates of the time; however, it is in excellent agreement with the age of 4.5 billion years, generally accepted in the past few years. Koczy simultaneously engaged in a variety of scientific projects involving many disciplines; he cultured plankton on a large scale, investigated the factors influencing light propagation in sea water and the relationship of light levels and biological activity, and was one of the earliest users of underwater photography as a scientific tool.

Shortly after the end of the Second World War, when plans for the now-famous Swedish deep-sea expedition of 1947-48 were approved, Koczy played an important part in the preparations; he was especially active in the conversion of the *Albatross* into a research vessel and in the acquisition of scientific equipment, particularly difficult at that time. He participated in the entire fifteen month expedition which greatly profited from his scientific insight and experimental skill. The organization and analysis of the experimental material collected during the expedition occupied Koczy for several years. He assumed responsibility for processing, analysing and publishing the extensive echo-sounding records. Koczy developed a unique method for obtaining water samples close to the ocean floor, which could be used even at great depths; the samples obtained in this manner yielded results which established him as a pioneer in the study of the properties of deep oceanic waters. Most important, however, was

that Koczy was able to formulate his ideas about the geochemical balance of the radioactive elements in the hydrosphere on the basis of his measurements of radionuclides in oceans and sediments.

In 1957 Koczy accepted an invitation from Dr F. G. Walton Smith, director of the Institute of Marine Sciences, University of Miami, to go to Miami to develop a division of physical sciences. Here he assembled a large group of world famous research scientists engaged in activities ranging from underwater acoustics to the study of radionuclides produced in sediments by cosmic rays. His efforts were very important in making the institute one of the world's leading oceanographic research centres. Koczy felt a strong obligation to establish a good teaching programme and he was instrumental in making the institute one of the best in the training of graduate students.

While at the University of Miami, Koczy continued his investigations of natural radionuclides in sea water and sediments. He became a leading authority on age determination of ocean sediments. Under his direction a dating method was developed which was based on the ratios of the activities of protactinium-231 (a daughter nuclide of uranium-235) and thorium-230 (a daughter of uranium-239); capable of dating sediments up to 200,000 years old, it is the most commonly used and reliable of the various geochronological methods. Koczy also showed that the concentration of radium-226 in the oceans was too great to be derived from land sources. He proposed that the radium diffused from the ocean sediments (this was a particularly important discovery, for radium-226 is the only natural radioactive tracer released in quantity at the bottom of the ocean). On the basis of the vertical distribution of concentrations of radium, Koczy calculated vertical mixing rates for deep ocean waters and the time of residence of these water masses.

Koczy never dismissed the practical side of his work because of his profound understanding of the social functions of science. He became concerned with, for example, the relationship of oceanography to fisheries and radioactive waste disposal at sea. His capabilities and his concern for the development of science naturally led to an involvement with scientific policy on a national level. Koczy was appointed early a member of the National Academy of Sciences Committee on Oceanography and for four years was one of its most active and enthusiastic members. In the same period, he sat with the Earth Sciences Advisory Panel of the National Science Foundation. He also held advisory positions with the Atomic Energy Commission, the Environmental Sciences Service Administration and Bureau of Commercial Fisheries. In addition, he was on the editorial boards of many scientific publications. Koczy was involved in one of oceanography's most imaginative investigations of the sea, the Joint Oceanographic Institutes Deep-Earth Sampling, the purpose of which was to drill into the ocean floor to obtain long core samples in an effort to expand the understanding of the origin and history of the ocean basins. Koczy was also chairman of the Gulf Universities Research Corporation, an organization devoted to oceanographic investigations of the Gulf of Mexico and the Caribbean through the co-operative efforts of universities in the area.

Although a dedicated scientist, Koczy took a great interest in cultural activities throughout his life. His colleagues in Vienna recall that he was a voracious reader and frequently visited the theatres and museums; he is reputed to have attended almost every concert of the Vienna Philharmonic Orchestra in his student days. At the time of his death he was on leave from the University of Miami and was a distinguished visiting professor at the University of Hawaii.

## University News:

### Leeds

DR MARTIN LÖB has been awarded the title of professor of mathematical logic and Dr David Clayson has been awarded the title of professor in the Department of Experimental Pathology and Cancer Research.

### London

DR J. S. WILKIE, reader in the history and philosophy of science, has been appointed to the chair of history and philosophy of science at University College, and the title of professor of internal combustion engineering has been conferred on Dr Wei-Tze Lyn in respect of his post at King's College.

### Reading

DR H. H. HOPKINS, at present a reader in applied optics in the Imperial College of Science and Technology, has been appointed first holder of the chair of applied optics in the Department of Applied Physical Sciences.

### Welsh College of Advanced Technology

DR R. W. EDWARDS, head of the Pollution Division at the Ministry of Technology Water Pollution Research Laboratory, has been appointed professor and head of the Department of Applied Biology, Welsh College of Advanced Technology (University of Wales Institute of Science and Technology (Designate)).

## Appointments

PROFESSOR R. HIDE, professor of geophysics and physics at the Massachusetts Institute of Technology, has been appointed to a senior post in the Meteorological Office where he will direct a new laboratory of geophysical fluid dynamics.

PROFESSOR A. W. KAY, University Department of Surgery, Western Infirmary, Glasgow, and Professor R. A. Gregory, Physiological Laboratory, Liverpool, have been appointed to the Medical Research Council in succession to Sir Hedley Atkins and Professor W. D. M. Paton.

## Announcements

DR J. NAPIER of the University of London has been appointed by the Smithsonian Institution to examine the feasibility of establishing an International Centre for the Study of Primate Animals.

THE newly instituted Royal Society Mullard Award, consisting of a gold medal and a prize of £1,000, is to be presented to Dr G. D. H. Bell, director of the Plant Breeding Institute, Cambridge, for his contributions to agricultural production in breeding the Proctor barley.

AN International Society for Developmental Psychobiology is being formed to facilitate communication among research workers interested in relating biological processes to behaviour in the developing organism. Further information can be obtained from Dr B. J. Key, Department of Neuropharmacology, Medical School, Birmingham 15.

MR RONALD W. CLARK of 10 Campden Street, London, W.8, is writing a biography of Sir Edward Appleton and wishes to hear from persons who have material or information to contribute.

## Meetings

PURE and Applied Chemistry, September 4-10, Prague (Organizing Committee, XXIst International Congress of Pure and Applied Chemistry, POB 139, Praha 6-Dejvice).

MOLECULAR Structure and Spectroscopy, September 5-9, The Ohio State University (Professor K. Narahari Rao, Molecular Spectroscopy Symposium, Department of Physics, The Ohio State University, 174 West 18th Avenue, Columbus, Ohio).

NUCLEAR Structure, September 7-13, Tokyo (Professor M. Sakai, Institute for Nuclear Study, University of Tokyo, Tanashi-machi, Kitatama-gun, Tokyo).

SYMPOSIUM of the British Society of Scientific Glassblowers, September 8-9, University of Reading (J. A. Frost, 3 Grass Hill, Caversham, Reading, Berks.).

WAVES in Plasma, September 11-13, Culham Laboratory (The Meetings Officer, the Institute of Physics and the Physical Society, 47 Belgrave Square, London, SW1).

GROWTH Hormone, September 11-13, Milan (Dr. A. Pecile, Secretary of International Symposium on Growth Hormone, Via A del Sarto, 21, Milan).

THIN Walled Steel Structures Symposium, September 11-14, University College of Swansea (Symposium Office, c/o SSIDA, Albany House, Petty France, London, SW1).

HIGH Voltage Insulation in Vacuum, September 13-14, Institution of Electrical Engineers (The Meetings Officer, the Institute of Physics and the Physical Society, 47 Belgrave Square, London, SW1).

ELECTRON Optics, Instrumentation and Quantitative Electron Microscopy, September 19-21, University of St. Andrews (The Meetings Officer, the Institute of Physics and the Physical Society, 47 Belgrave Square, London, SW1).

INDUSTRIAL Production of Plants, September 20-22, Vienna (Ruthner Industrieanlagen für Pflanzenbau, Gesellschaft m.b.H., Wien II, Obere Donaustrasse 49-51).

USE of Radioactive Isotopes in Pharmacology, September 20-23, Geneva (Secrétariat général de la Conférence, 20 bd. d'Yvoy, 1211 Geneva 4).

INTERNATIONAL Spectrometry Conference, September 25-29, Technical University, Berlin (Dr W. Fritzsche, Gesellschaft Deutscher Chemiker, 6000 Frankfurt (M) Postfach 9075).

CARBOHYDRATE Discussion Group (a Chemical Society Subject Group), September 26, London (Dr R. D. Guthrie, The Chemical Laboratory, University of Sussex, Brighton).

VERTEBRATE Palaeontology and Comparative Morphology, September 27-28, Queen Elizabeth College, University of London (Dr C. B. Cox, Department of Zoology, King's College, Strand, London, WC2).

Low Energy Nuclear Physics, September 27-29, University of Manchester (The Meetings Officer, the Institute of Physics and the Physical Society, 47 Belgrave Square, London, SW1).

PROBLEMS of Birds as Pests, September 28-29, Royal Geographical Society, Kensington Gore, London (The Institute of Biology, 41 Queen's Gate, London, SW7).

ERRATUM. In the article "The Flow Behaviour of Blood in the Circulation" by R. L. Whitmore (*Nature*, 215, 123; 1967) equation 5 should read

$$\eta_{\text{eff}} = \frac{\eta_p}{1 - \left(\frac{R-4}{R}\right)^4 \left(1 - \eta_{rc}\right)}$$

Line 1 in the right-hand column on page 126 should read "... the asymptotic values should be 25 per cent", and the last author in reference 19 should be spelt Salzman.

## APPOINTMENTS VACANT

APPLICATIONS are invited for the following appointments on or before the dates mentioned:

**TECHNICAL ASSISTANT** to take part in a research project into the structure and function of invertebrate nervous systems using various modern techniques—Prof. G. M. Hughes, Department of Zoology, The University, Bristol, 8 (August 1).

**RESEARCH ASSISTANT** in the DEPARTMENT OF SOCIOLOGY—The Registrar, University of Essex, Wivenhoe Park, Colchester, Essex (August 4).

**RESEARCH ASSISTANT** in the CHEMISTRY DEPARTMENT for an investigation of the synthesis of new unsaturated carbohydrate derivatives for testing as anti-tumour agents—Prof. L. Hough, Queen Elizabeth College (University of London), Campden Hill Road, London, W.8 (August 5).

**EDITORIAL ASSISTANTS** (with a good degree in chemistry and for some duties a working knowledge of languages would be an asset) for various duties with the Society's scientific publications—The Editor, The Chemical Society, Burlington House, Piccadilly, London, W.1 (August 10).

**LECTURERS or ASSISTANT LECTURERS** (2) in the DEPARTMENT OF ELECTRICAL ENGINEERING and ELECTRONICS (candidates for one of the posts should be specialists in the field of control engineering)—The Registrar, The University, Liverpool, quoting Ref. RV/87 (August 10).

**ASSISTANT EXPERIMENTAL OFFICER** (with a degree in botany, chemistry or a related subject) in the ENTOMOLOGY SECTION to participate in studies on the behaviour of dipterous pests; and an **ASSISTANT EXPERIMENTAL OFFICER** (with a degree in botany, chemistry or a related subject) in the PLANT PHYSIOLOGY SECTION to assist with work on the extraction and purification of plant hormones and the study of their physiological properties—The Secretary, National Vegetable Research Station, Wellesbourne, Warwick (August 11).

**RESEARCH ASSISTANT** (with a degree in botany, biochemistry, microbiology or genetics, and a special interest in biochemical genetics, particularly enzymology) in the DEPARTMENT OF BOTANY—The Secretary, University College London, Gower Street, London, W.C.1 (August 11).

**COMPUTING ASSISTANT** to assist members of staff and postgraduate students in the DEPARTMENT OF MECHANICAL ENGINEERING in the development and operation of ALGOL programmes for the University KDF9 computer—The Registrar and Secretary, The University, Leeds, 2 (August 12).

**ASSISTANT EXPERIMENTAL OFFICER** (graduate with an interest in the physiological aspect of host-parasite relations would be suitable) in the MYCOLOGY SECTION for work on the grey mould diseases of soft fruit and tomatoes—The Secretary, Scottish Horticultural Research Institute, Invergowrie, Dundee (August 14).

**ASSISTANT KEEPER** (with an appropriate degree which should include botany and/or the Diploma of the Museums Association) of NATURAL HISTORY—The Director, Castle Museum, Norwich, NOR 65B (August 14).

**LECTURER (Clinical)** in the DEPARTMENT OF PATHOLOGY—The Assistant Registrar, The Medical School, University of Birmingham, Birmingham, 15 (August 14).

**LECTURER** (preferably with an interest in any aspect of fungi) in the DEPARTMENT OF BOTANY—Head of the DEPARTMENT OF BOTANY, The University, Newcastle upon Tyne 1 (August 14).

**RESEARCH ASSISTANT** (with a Ph.D. degree or equivalent) in the DEPARTMENT OF CHEMISTRY for work on the synthesis of a naturally occurring polypeptide—The Secretary, University of Exeter, Northcote House, The Queen's Drive, Exeter, Devonshire (August 14).

**RESEARCH FELLOW** (medically qualified and preferably holding the D.P.M.) in PSYCHIATRY—Prof. W. H. Trethowan, Department of Psychiatry, Queen Elizabeth Hospital, Birmingham, 15 (August 14).

**S.R.C. POSTDOCTORAL RESEARCH FELLOW** (with considerable experimental experience in either physical gas dynamics including shock tube research, atomic and molecular beams, measurements of collision cross sections or ion detection and analysing systems) in the DEPARTMENT OF PURE AND APPLIED PHYSICS—Dr R. M. Hobson, Department of Pure and Applied Physics, University of Belfast, Northern Ireland (August 14).

**ASSISTANT LECTURER in PHILOSOPHY**—The Registrar, The University, Canterbury, Kent, quoting Ref. A/69 (August 15).

**RESEARCH ASSISTANT** in the DEPARTMENT OF STATISTICS—The Registrar, University College of Wales, Aberystwyth (August 16).

**LECTURER in BIOLOGY** in the DEPARTMENT OF APPLIED MICROBIOLOGY AND BIOLOGY—The Registrar, University of Strathclyde, George Street, Glasgow, C.1, quoting Ref. 66/67 (August 18).

**SENIOR RESEARCH OFFICER** (with research experience in some branch of engineering) in the DEPARTMENT OF APPLIED MATHEMATICS for research in rheology—The Registrar, University College of Wales, Aberystwyth (August 19).

**ASSISTANT LIBRARIAN** (with an honours degree, and preferably some experience in dealing with scientific material)—The Secretary, University of Exeter, Northcote House, The Queen's Drive, Exeter, Devonshire (August 21).

**CHAIR OF PHYSIOLOGY** at St. Mary's Hospital Medical School—The Academic Registrar, University of London, Senate House, London, W.C.1 (August 21).

**SENIOR LECTURER** and a **LECTURER in MATHEMATICS** at the University College of Rhodesia—The Inter-University Council, 33 Bedford Place, London, W.C.1 (August 21).

**ASSISTANT LECTURER** in the DEPARTMENT OF MEDICINE, Royal Infirmary—The Professor of Medicine, Department of Medicine (University of Edinburgh), The Royal Infirmary, Edinburgh (August 25).

**LECTURER** (preferably with a medical qualification) in PHARMACOLOGY—The Secretary, The Middlesex Hospital Medical School, London, W.1 (August 25).

**LECTURERS or ASSISTANT LECTURERS** (2) (with research interests in any branch of applied mathematics) in the DEPARTMENT OF APPLIED MATHEMATICS, St. Salvator's College—The Secretary, University of St. Andrews, College Gate, St. Andrews, Fife, Scotland (August 25).

**SENIOR LECTURER in VETERINARY SCIENCE** at the University of Queensland, Australia—The Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (London and Brisbane, August 25).

**LECTURER or ASSISTANT LECTURER** (preferably with a research interest in topology) in the DEPARTMENT OF MATHEMATICS—The Registrar, University College of Wales, Aberystwyth (August 26).

**SENIOR LECTURER** (with research and/or industrial experience in fluid dynamics and preferably holding a higher degree) in FLUID MECHANICS in the DEPARTMENT OF MECHANICAL ENGINEERING—The Registrar, University of Strathclyde, George Street, Glasgow, C.1 (August 30).

**FELLOW in CELL BIOLOGY** to study the biochemical self sufficiency of chloroplasts—The Registrar, The University of York, Heslington, York (August 31).

**LECTURER in COMPARATIVE EDUCATION**—The Secretary, University of London Institute of Education, Malet Street, London, W.C.1 (August 31).

**LECTURER or ASSISTANT LECTURER in APPLIED MATHEMATICS**—The Registrar, The University, Senate House, Bristol, 2 (August 31).

**LECTURER** (with a good honours degree in physics, electronics or electrical engineering and research or teaching experience in some aspect of the electrical properties of materials) in MATERIALS SCIENCE—The Registrar, University College of North Wales, Bangor, North Wales (August 31).

**LECTURERS/SENIOR LECTURER in PURE MATHEMATICS** at the University of Sydney, Australia—The Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (Australia and London, August 31).

**SENIOR LECTURER in INSECT PHYSIOLOGY** in the DEPARTMENT OF ENTOMOLOGY, University of Queensland, Australia—The Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (London and Brisbane, August 31).

**CHAIR of MATERIALS** in the FACULTY OF ENGINEERING at Queen Mary College—The Academic Registrar, University of London, Senate House, London, W.C.1 (September 7).

**CHAIR of NUCLEAR ENGINEERING** at Queen Mary College—The Academic Registrar, University of London, Senate House, London, W.C.1 (September 7).

**LECTURER or ASSISTANT LECTURER** (registered member of the veterinary profession) in the DEPARTMENT OF VETERINARY PATHOLOGY—The Secretary, University of Edinburgh, Old College, South Bridge, Edinburgh (September 16).

**LECTURER or ASSISTANT LECTURER** (with interests in any of the major economic fields of geology) in the DEPARTMENT OF GEOLOGY—The Secretary, University of Edinburgh, Old College, South Bridge, Edinburgh (September 16).

**ASSISTANT LECTURER** (with a good honours science degree, preferably in biochemistry, and preferably some postgraduate research experience) in the DEPARTMENT OF CHEMICAL PATHOLOGY—The Secretary, The University, Aberdeen (September 30).

**CHAIR and HEADSHIP of the DEPARTMENT of APPLIED MINERAL SCIENCES**, Houldsworth School of Applied Science—The Secretary, The University, Leeds, 2 (September 30).

**ENTOMOLOGISTS** (2) (with an honours degree in biology with emphasis on entomology and practical postgraduate experience, preferably in biocontrol) at the COMMONWEALTH INSTITUTE OF BIOLOGICAL CONTROL for field work on biocontrol projects—The Secretary, Commonwealth Agricultural Bureaux, Farnham House, Farnham Royal, Buckinghamshire (October 15).

**HEAD TECHNICIAN** (with wide experience in the techniques of normal or pathological histology and preferably F.I.M.L.T. or equivalent qualifications) for the Laboratory of Cytopathology—The Personnel Officer, National Institute for Medical Research, Mill Hill, London, N.W.7.

**HEAD** (virologist of wide experience with a knowledge of immunology, and preferably with a medical qualification) of the VIRUS VACCINES DEPARTMENT, Lister Institute of Preventive Medicine, Elstree, Herts.—The Secretary, Lister Institute of Preventive Medicine, Chelsea Bridge Road, London, S.W.1.

**LECTURER in GEOGRAPHY** to specialize in human geography and in the regional geography of either Africa or Asia in the Department of Arts, Science and Education—The Registrar, University of London, Goldsmiths' College, New Cross, London, S.E.14.

**POSTDOCTORAL FELLOW** (preferably with some experience of the chemistry of phenols and/or quinones) in the DEPARTMENT OF ORGANIC CHEMISTRY, for research into the preparation, properties and uses of quinone-methides—The Registrar, The University, Liverpool, 3, quoting Ref. RV/88.

**RESEARCH ASSISTANT (Biochemist)** (preferably graduate in chemistry, biochemistry or physiology) for an investigation of oestrogens in relation to infertility—The Group Secretary, Romford H.M.C., Oldchurch Hospital, Romford, Essex, quoting Ref. No. 25/103.

**RESEARCH ASSISTANT** (preferably honours graduate chemist) to join in chemical studies of human arterial disease (atheroma)—Dr C. J. W. Brooks, Chemistry Department, University of Glasgow, Glasgow, W.2.

**RESEARCH ASSISTANT** (with a good honours degree in mathematics) in the DEPARTMENT OF APPLIED MATHEMATICS and MATHEMATICAL PHYSICS to carry out theoretical research, which could lead to the degree of Ph.D., on "The Effects of High Electric Fields of Semiconductors"—Dr Alan R. Beattie, Department of Applied Mathematics and Mathematical Physics, University College, Cardiff.

**RESEARCH ASSISTANTS** in a wide range of projects in the following departments: Computing and Cybernetics; Management and Business Studies (particularly in the fields of multi-access systems and the theory of automata); Applied Physics; Applied Chemistry; Pharmacy; Mechanical and Production Engineering; Electrical and Electronic Engineering; Civil Engineering and Building—The Registrar, Brighton College of Technology, Moulsecomb, Brighton 7, Sussex.

**TECHNICIAN (O.N.C. or equivalent qualification, and preferably some experience of bacteriology)** in the DEPARTMENT OF GENETICS—Prof. R. H. Pritchard, The University, Leicester.

## HOW TO BUY NATURE

Volumes start in January, April, July and October, but subscriptions may begin with any issue.

The direct postal price per subscription for one or two copies of NATURE each week is:

**\*12 MONTHS** (52 issues and 4 indexes)

Great Britain and Eire.....**£14.0.0** each  
United States of America.....(by air freight).....**\$44** each  
Canada.....(by air freight).....**\$47.80** each  
Elsewhere overseas by surface mail.....**£13.15.0** each  
(Charge for delivery by air mail on application)

\*Shorter periods *pro rata*. (Minimum three months.)

### MULTIPLE SUBSCRIPTIONS

For subscribers who take more than two copies of NATURE each week these reduced annual rates are offered:

**12 MONTHS** (52 issues and 4 indexes)

Number of Copies	G.B. & Eire	U.S.A. (by air freight)	Canada (by air freight)	Elsewhere (surface mail)
3-5	Each <b>£13.10.0</b>	Each <b>\$42</b>	Each <b>\$46.00</b>	Each <b>£13.10.0</b>
6-11	<b>£12.15.0</b>	<b>\$40</b>	<b>\$43.60</b>	<b>£12.15.0</b>
12 or more	<b>£12.0.0</b>	<b>\$38</b>	<b>\$41.70</b>	<b>£12.0.0</b>

Multiple subscriptions must run concurrently. Every copy will be posted separately, and for speed of delivery each subscription can be addressed to a different individual, or department at the same address. (ZIP essential for U.S.A.)

# Newmatic

Meet PR-6, the world's newest, most advanced refrigerated blood-bank and general purpose centrifuge. Completely automatic. All you do is set time, speed, and turn the master control knob. Our solid-state control system oversees the rest. And as for speed, our new windshielded horizontal blood bag head attains 5500 rpm and 7000 g. Other features: precise feedback speed control; temperature range from  $-30^{\circ}\text{C}$  to  $+30^{\circ}\text{C}$ ; dynamic braking that halves stopping time; and a featherweight spring-balanced cover that won't shut unexpectedly. One more thing. This new compact not only accepts all PR-2 accessories, it virtually doubles their g-force. Send for Bulletin PR-6. We'll send you the facts on the double.

**INTERNATIONAL  
EQUIPMENT CO.**

### Classified Advertisements

Semi-displayed £4 16s. per single column inch. Minimum £2, each additional 1/12th of an inch 8s. Full page £132. Half page across £66. Colour (orange) £15 extra. 1s. is charged for the re-direction of replies to advertisements with a box number.

ADVERTISEMENTS SHOULD BE ADDRESSED TO: T. G. Scott and Son, Limited, 1 Clement's Inn, Strand, London, W.C.2. Telephone: 01-405 4743. Telegrams: Textualist, London, W.C.2.

### APPOINTMENTS VACANT

#### NATIONAL INSTITUTE FOR RESEARCH IN DAIRYING (UNIVERSITY OF READING) BACTERIOLOGY DEPARTMENT

Biochemist or microbiologist, preferably with experience of immunology, required for a group working on natural defence mechanisms of the udder against mastitic pathogens, in particular staphylococci. The group works in close association with a team working on the control of mastitis. The natural inhibitors and antibodies present in bovine blood stream, milk and the mammary gland are under study. The department is well equipped and facilities are available for the use of conventional and germ-free animals. Arrangements exist for registration for a Higher Degree. Appointment to grade of Scientific Officer (£926 to £1,574) or Senior Scientific Officer (£1,744 to £2,155) according to age and experience.

Apply to Secretary, N.I.R.D., Shinfield, Reading, naming two referees and quoting reference 67/25. (268)

#### BRAIN WAVES

There is a vacancy for a

#### TRAINEE ELECTRO- ENCEPHALOGRAPHY TECHNICIAN

in a regional centre based on Goodmayes Hospital, Ilford, Essex. The work involves recording of brain activity by means of electrodes on the head, as an aid to diagnosis, and requires an ability to deal with people as well as some interest in electronic apparatus. Salary during training is £260 to £520 according to age (16 to 24) plus London weighting. (Furnished accommodation may be available.) Educational requirements are G.C.E. "O" levels in English Language, Mathematics, and a Science subject.

For details apply to:  
The Secretary,  
Goodmayes Hospital,  
Barley Lane,  
Goodmayes,  
Ilford, Essex. (421)

#### ROWETT RESEARCH INSTITUTE

BUCKSBURN, ABERDEEN

#### MICROBIOLOGY DEPARTMENT

Applications are invited for a post on the **Scientific Officer/Senior Scientific Officer** scale. The post is concerned with extension of work on the nitrogen metabolism of micro-organisms in rumen contents using stable isotopes of N and <sup>14</sup>C and <sup>3</sup>H. Applicants should have a degree in microbiology or in biochemistry or chemistry with experience in microbiology. Salary according to experience within the range S.O. £926 to £1,574 or S.S.O. £1,744 to £2,155. Superannuation under F.S.S.U. Further particulars are available.

Applications, including the names of three referees, should be lodged with the Secretary of the Institute within one month. (329)

## Scientific Civil Service

### DEPARTMENT OF AGRICULTURE AND FISHERIES FOR SCOTLAND

MARINE LABORATORY, Aberdeen

**MICROBIOLOGIST/BIOLOGIST/BIOCHEMIST** (graded S.S.O./S.O./Research Fellow (Junior or Senior)) required for programme on fish diseases and pathology (initially concerning the diseases of salmonid fish). Candidates should possess experience in bacteriology or virology. Post-graduate experience preferred but not essential.

**MARINE ECOLOGIST** (graded E.O./A.E.O., for man only) required to join a team working on the ecology and population dynamics of herring and other pelagic fishes. In addition to laboratory work the post will involve periods of duty at sea aboard research vessels and commercial fishing vessels.

#### QUALIFICATIONS

Research Fellows: Applicants should have the qualifications required for S.O. and must have reached a high standard of research ability. In addition the following are required: Junior R.F.—2 years' post-graduate research. Senior R.F.—3 years' post-graduate research.

#### SALARY

Junior R.F. fixed in range £1,180 to £1,575;

Senior R.F. fixed in range £1,745 to £2,155.

Except in the case of Research Fellowships, which are tenable for three years, the above posts carry prospects of permanent pensionable appointments.

**APPLICATION FORMS** and further particulars from Establishment Officer, Department of Agriculture and Fisheries for Scotland, Room 172, St. Andrew's House, Edinburgh 1. Closing date for receipt of applications August 21, 1967.

## MINISTRY OF TECHNOLOGY

### TORRY RESEARCH STATION

P.O. Box 31, 135 Abbey Road, Aberdeen

**MICROBIOLOGIST** (graded E.O./A.E.O.) to work on microbiology of fish and fishery products and associated projects such as biochemical aspects of bacterial toxonomy.

Prospect of permanent pensionable appointment.

**APPLICATION FORMS** from the Director at the above address, quoting E/AT/043. Closing date August 14, 1967.

#### SALARIES, QUALIFICATIONS and AGE LIMITS

##### SCIENTIFIC OFFICER/SENIOR SCIENTIFIC OFFICER

**SALARIES:** S.O.: £926–£1,574. (Increments and special £120 award for approved post-graduate experience.)

S.S.O.: £1,744–£2,155. (Starting salary may be above minimum.) Most Scientific Officer Class appointments carry promotion prospects to Principal Scientific Officer: £2,250–£3,107. Salaries are supplemented in the London area.

#### QUALIFICATIONS:

S.O.: 1st or 2nd class hon. degree or equivalent or higher qualifications in appropriate subject. Age under 29.

S.S.O.: As above plus at least 3 years' post-graduate research. Age normally 26–31.

##### ASSISTANT EXPERIMENTAL OFFICER/EXPERIMENTAL OFFICER

**SALARIES:** A.E.O.: £568 (age 18)–£803 (age 22)–£1,017 (age 26)–£1,243. E.O.: £1,365–£1,734. Most Assistant Experimental Officers become Experimental Officers before reaching A.E.O. scale maximum. Promotion prospects to Senior Experimental Officer: £1,977–£2,411. Salaries are supplemented in the London area.

#### QUALIFICATIONS:

Degree, H.N.C., or equivalent in appropriate subject. Under 22, minimum qualification is G.C.E. in five subjects; including two Scientific/Mathematical subjects at 'A' level or equivalent level.

A.E.O.: age 18–27, E.O.: normally 26–30.

A free booklet entitled "THE SCIENTIFIC CIVIL SERVICE" is available on request from Civil Service Commission, Savile Row, London, W.1. (379)

**MONASH UNIVERSITY**

MELBOURNE, AUSTRALIA

CHEMICAL ENGINEERS, PHYSICAL  
CHEMISTS, BIOCHEMISTS

Applications are invited for three posts as Lecturer/Senior Lecturer in the Department of Chemical Engineering. A previous current advertisement for one of these posts indicated the preferred field to be either FOOD AND BIO-CHEMICAL ENGINEERING or THERMODYNAMICS AND EXTRACTIVE METALLURGY. Additional candidates are now sought with ability in DIFFUSIONAL SEPARATION PROCESSES, or in TRANSPORT PHENOMENA or in EXPERIMENTAL CHEMICAL KINETICS. Good candidates with interests in other areas, including mathematics with a strong interest in chemical engineering, will also be considered. The Department is well housed in a new building. Good computing facilities are available.

Current salary scales are: Senior Lecturer, \$A6,500 to \$A7,600 per annum; Lecturer, \$A4,800 to \$A6,300 per annum, but salaries are at present under review and it is expected that the maximum of the Senior Lecturer scale will be increased to \$A8,750 per annum, with relative increases through the scale, and the Lecturer's range will become \$A5,400 to \$7,300. Superannuation on the F.S.S.U. basis is provided.

Benefits: Full travelling expenses for an appointee and family; removal allowance; repatriation after three years if desired; initial subsidized housing; availability of loans for home purchase; STUDY LEAVE is granted at the rate of one term's leave for six months' service, with provision for financial assistance.

Further general information is available from the Academic Registrar, Monash University, Clayton, Victoria, Australia, or the Secretary-General, Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1. Technical inquiries to Professor O. E. Potter, Chairman, Department of Chemical Engineering of the University. Closing date: September 15, 1967. The University reserves the right to make no appointment, or to appoint by invitation. (418)

**UNIVERSITY OF SHEFFIELD**DEPARTMENT OF METALLURGY  
APPOINTMENT OF AN ELECTRON  
MICROSCOPIST (EXPERIMENTAL  
OFFICER)

Applications are invited for the post of Electron Microscopist (Experimental Officer) in the Department of Metallurgy. Candidates must possess a university degree or equivalent and must have experience in the maintenance and use of modern electron microscopes. The successful candidate will have a special responsibility for two high resolution electron microscopes; he will be expected to develop improved techniques for the study of complex metallic structures and to apply them to researches in progress in the Department. Initial salary according to qualifications and experience in the range: Experimental Officer, £915 to £1,415; Senior Experimental Officer, £1,470 to £2,410, with F.S.S.U. provision.

Further particulars from the Registrar, to whom applications (4 copies) should be sent not later than August 31, 1967. (373)

**UNIVERSITY OF LEEDS**DEPARTMENT OF MECHANICAL  
ENGINEERING  
COMPUTING ASSISTANT

Applications are invited for the post of Computing Assistant in the Department of Mechanical Engineering. The successful applicant will be required to assist members of staff and postgraduate students in the Department of Mechanical Engineering in the development and operation of ALGOL programmes for the University KDF9 Computer. Full participation in a wide range of research projects will be encouraged. Previous experience of programming and/or numerical analysis applicable to engineering would be an advantage. Salary according to age, qualifications and experience, in the range of £915 to £2,050 per annum.

Applications (three copies), stating age, qualifications and experience, and naming three referees, should reach the Registrar and Secretary, The University, Leeds, 2 (from whom further particulars may be obtained), not later than August 12, 1967. (372)

**WATER RESOURCES BOARD****Freshwater Biological Association  
UNIVERSITY OF LANCASTER**

The Water Resources Board in conjunction with the Freshwater Biological Association and the University of Lancaster invite applications from those who are appropriately qualified for the following appointments:

**1. A PRINCIPAL SCIENTIFIC OFFICER  
(£2,250 to £3,107)****or SENIOR SCIENTIFIC OFFICER**

**(£1,744 to £2,155)** who would be responsible for the biological aspects of the Morecambe Bay Barrage Feasibility Study. He would be stationed at the Freshwater Biological Association's Windermere laboratory. His work would be complementary to that of the consulting engineers, whose study will take about three years and is estimated to cost about £500,000. He would investigate and advise on the effects of proposed engineering works on the ecology of the area with particular reference to:

- (a) the effects on migratory fish in the rivers flowing into the Bay;
- (b) the changes in the animal and plant communities likely to result from the conversion of a salt-water estuary into a freshwater lake or lagoons, and any practical problems to which these changes might give rise;
- (c) the existing sea water fisheries.

**2. A RESEARCH STUDENT**

to work with the above who would be based, if eligible, and may register for a higher degree at Lancaster University.

The appointments to these two posts will be considered together. Thus if a zoologist who had experience in the ecology of fresh or estuarial waters, or an interest in migratory fish, were appointed to post no. 1, the junior post might be held by an honours graduate wishing to pursue research for a higher degree on the higher plant or algal ecology of the area. Alternatively, a primarily botanical ecologist with sufficient qualifications and a suitable breadth of experience would be considered for post no. 1; such a person might be assisted by a research student working on a particular problem within the wider field, for example, the effects on migratory fish. A certain amount of travelling will probably be involved.

The appointments will commence from September or October 1967. The higher post will be for three years and the research studentship will be tenable for two to three years.

Applications (three copies) together with the names of two referees, should be sent by Saturday, August 19, 1967, for post no. 1 to The Director, Freshwater Biological Association, The Ferry House, Ambleside, Westmorland, and for post no. 2, to Biology Department, University of Lancaster, St. Leonard's House, Lancaster.

(389)

**UNIVERSITY OF LONDON**CHAIR OF NUCLEAR ENGINEERING AT  
QUEEN MARY COLLEGE

The Senate invite applications for the Chair of Nuclear Engineering tenable at Queen Mary College (salary not less than £3,570 a year plus £100 London Allowance).

Applications (10 copies) must be received not later than September 7, 1967, by the Academic Registrar, University of London, Senate House, W.C.1, from whom further particulars may be obtained. (412)

**ST. BARTHOLOMEW'S HOSPITAL  
LONDON, E.C.1**

**SENIOR RESEARCH TECHNICIAN** required for interesting and varied work on immunity in reticuloses and other malignant diseases. Associates of the Institute of Medical Laboratory Technology with a diploma in haematology would find ample opportunity and material for a thesis. Whitley Council Salary Scales.

Write, naming two referees, to the Clerk to the Governors, quoting Project No. 863, Ref. ASC/1089. (406)

## TECHNICIANS

"Shell" Research Limited have vacancies for **TECHNICIANS** in the Product Evaluation and Plant Pathology Divisions of their Woodstock Agricultural Research Centre, Sittingbourne, Kent.

Candidates should have reached H.N.C. level in a biological subject. An additional asset would be a qualification in the field or agriculture, while some experience of Parasitology, Malacology, or of Pesticides generally would also be advantageous. Candidates should be prepared to carry out both laboratory and field work and, occasionally, to travel in the U.K. or abroad.

Fringe benefits include an excellent pension scheme, staff restaurant, and a sports/social club.

*Apply in writing, giving brief details of age, qualifications, and experience, to:*

**Personnel Division,  
"Shell" Research Limited,  
Woodstock Agricultural Research Centre,  
SITTINGBOURNE, Kent.**

(369)

## INTERNATIONAL FLAME RESEARCH FOUNDATION

### RESEARCH INVESTIGATORS

Applications are invited for the posts of Research Investigators to work at the Central Research Station of the Foundation at Ijmuiden in Holland. The successful candidates who will preferably have a Ph.D. Degree in Physics or Engineering, are expected to join a small team of postdoctoral investigators to work on problems of combustion physics, in particular aerodynamics and heat transfer aspects of turbulent flames. The work of the Foundation involves frequent contacts on an international level with research scientists working in similar fields, and the Foundation encourages publication of high quality original work.

Starting Salary: £1,600 per annum. There are additional emoluments payable, including pension contribution, holiday bonus, costs of removal, etc. There is assistance with housing.

(390)

Applicants should write in the first place to:  
**Professor J. M. Beer,  
Department of Fuel Technology and  
Chemical Engineering,  
University of Sheffield,  
Mappin Street, Sheffield 1.**

## NORTHERN POLYTECHNIC HOLLOWAY, LONDON, N.7

Applications are invited for appointments as **RESEARCH ASSISTANTS** in **MATHEMATICS**. Candidates should have a First or Second Class Honours Degree in Mathematics or Statistics. The successful applicants will be expected to read for an M.Phil. or Ph.D. Degree in the field of either Statistics or Hydrodynamics. They will also be required to assist with the teaching in the Department for six hours per week.

**Salary scale, £810 by £30 to £870.**

Apply to the Head of the Department of Mathematics.

(398)

## UNIVERSITY OF SYDNEY

### LECTURERS/SENIOR LECTURERS IN PURE MATHEMATICS

Applications are invited for the above-mentioned positions. The teaching programme of the Department of Mathematics (Pure Mathematics) covers undergraduate pass and honours courses followed by courses leading to the M.Sc. and supervised research for the Ph.D. Currently research is in progress in group theory, representation theory, analysis and theory of numbers. For two of the vacancies preference will be given to applicants with research experience in topology or the use of computers in pure mathematics. The Department has ready access to the computers in the University's Basser Computing Laboratory. Salary for a Lecturer is within the range \$A4,800 by \$A220 to \$A6,340 per annum, and for a Senior Lecturer within the range \$A6,600 by \$A200 to \$A7,600 per annum. Academic salaries are at present under review.

Information concerning superannuation, housing scheme, sabbatical leave, etc., and method of application is obtainable from the Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1. Applications close in Australia and London on August 31, 1967. (416)

## ROYAL COLLEGE OF ART, S.W.7

### EXPERIMENTAL CARTOGRAPHY PROJECT

Applications are invited for the following two full-time posts as Research Fellows to form part of a small team concerned with the second stage of this project financed by the Natural Environment Research Council.

#### COMPUTER SCIENTIST PERCEPTION PSYCHOLOGIST

Salary within University lecturers' scale £1,530 to £2,690 per annum according to age and experience.

Further details and application form can be obtained from the Registrar, Royal College of Art, Kensington Gore, London, S.W.7. (420)

## UNIVERSITY OF QUEENSLAND

### SENIOR LECTURER IN VETERINARY MEDICINE

The University invites applications for the position of Senior Lecturer in Veterinary Medicine in the Department of Veterinary Clinical Studies. Applicants should hold a degree in veterinary science registrable by the Veterinary Surgeons' Board of Queensland and must have had experience in dairy cattle practice and/or swine practice. Higher degrees, publications, and teaching and administrative experience will be taken into account. The appointee will give courses of lectures on the diseases of cattle and of swine to final year students, will participate in dairy cattle and swine practice and in research studies on herd health. The salary range for a Senior Lecturer is \$A6,400 by \$A200 (6) to \$A7,600 per annum; however, academic salaries are presently under review. The University provides Superannuation similar to F.S.S.U., Housing Assistance, Study Leave and Travel Grants.

Additional information and application forms will be supplied upon request to the Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1. Applications close in London and Brisbane on August 25, 1967. (415)

## UNIVERSITY OF BELFAST

### EXPERIMENTAL OFFICER IN THE DEPARTMENT OF BOTANY

The Senate of The Queen's University of Belfast invites applications for the post of Experimental Officer. The salary scale is £1,000, rising by £50 per annum for 2 years to £1,100 by £55 per annum for 4 years to £1,320, and by £50 per annum for 2 years to £1,420. Initial placing on this scale will depend on qualifications and experience. The duties will include assistance in the teaching of techniques in microscopy, including electron microscopy and in research.

Letters of application (one copy), giving the names of two referees, should reach the Secretary, Academic Council, by August 18, 1967, from whom further details may be obtained. (426)

**UNIVERSITY OF WAIKATO**  
HAMILTON, NEW ZEALAND  
SENIOR LECTURESHIPS AND  
LECTURESHIPS

The University of Waikato invites applications for positions in the subjects listed below. Appointments may be made at the grade of Senior Lecturer, Lecturer, or Junior Lecturer.

GEOGRAPHY  
PSYCHOLOGY/SOCIOLOGY  
PURE MATHEMATICS

The salary scales are: Senior Lecturers, \$NZ4,600 to \$NZ5,400; Lecturers, \$NZ3,000 to \$NZ4,400; Junior Lecturers, \$NZ2,400 to \$NZ2,800. (\$NZ2=£1.) An applicant who is exceptionally well qualified in economics, geography, philosophy, psychology, sociology, or pure mathematics may be considered for an appointment as Reader at a salary between \$NZ5,800 and \$NZ6,600.

The University of Waikato began last year teaching full-time co-ordinated courses of study in the Schools of Humanities, Social Sciences and Education. It occupies a site of about 125 acres on the outskirts of Hamilton. The academic organization is based on schools of study rather than on faculties and departments. The development of postgraduate work and research is encouraged and conditions for study leave are favourable.

Conditions of appointment are available from the Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1. Applications close in New Zealand and London on August 28, 1967.

(424)

**ENGINEER or PHYSICIST**  
for

Medical Research Council

Additional members of scientific and technical staff are required for work on advanced electro-optical "input" devices. Salary between £1200 to £2200 depending on qualifications and experience.

For further information please write or telephone:

The Director,  
Clinical Effects of Radiation Research Unit,  
c/o 107 Sydney Street,  
London, S.W.3.

(380)

**UNIVERSITY OF PAPUA AND  
NEW GUINEA**

Staff will be required in 1968 for new posts at the levels of Tutor/Senior Tutor/Lecturer/Senior Lecturer in:

BIOLOGY, GEOGRAPHY, HISTORY OF  
SCIENCE AND TECHNOLOGY,  
MATHEMATICS

The university was established in 1965 and the first matriculated students started work this year. Appointees will have the opportunity to contribute to the development of courses appropriate to a new university in an emergent community; there will be opportunities for research and class groups will be small.

Salaries: Tutor, \$A3,820 to \$A4,300 per annum; Senior Tutor, \$A4,700 to \$A4,950 per annum; Lecturer, \$A5,300 to \$A6,840 per annum; Senior Lecturer, \$A7,100 to \$A8,100 per annum; plus \$A360 per annum for married appointees. F.S.S.U. type superannuation is available and accommodation will be provided at reasonable rental. Taxation rates are very substantially below those operating in Australia and the United Kingdom. There are special financial provisions for children attending secondary schools outside the territory.

Further details, including conditions of employment, travel and removal expenses provided, a general policy, statement on the purposes of the University, and information on the method of application may be obtained from the Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1, or from the Registrar of the University, P.O. Box 1144, Boroko, T.P.N.G., Closing date for applications: August 15, 1967.

(413)

**SIMON FRASER UNIVERSITY**  
**Research Opportunities**  
**in Chemistry**

The Department of Chemistry of this rapidly growing university, which is situated on the outskirts of the city of Vancouver, has openings for suitably qualified students in the graduate programme leading to the degrees of M.Sc. and Ph.D. Qualified students will be expected to have an honours degree in Chemistry, or A.R.I.C. Financial assistance in the form of teaching assistantships and research assistantships, to the value of \$3,100 per annum in the first year, will be available to suitable candidates. The trimester system in operation at Simon Fraser University allows students to enter the graduate programme in September or January.

*Interested persons should write in the first place to*

**The Chairman, Graduate Admissions Committee,  
Department of Chemistry,  
Simon Fraser University,  
Burnaby 2, B.C.,  
CANADA.**

(289)

**MICROBIOLOGIST**

with Ph.D. or equivalent, required for Senior Graduate Staff of the Group Research Laboratories. Candidates should have research experience in microbiological aspects of food technology, or of continuous culture and growth kinetics of yeasts and moulds and bacteria.

The successful candidate will be concerned with bacteriological research in food processes and will be expected to maintain contact with other research centres.

Salary and conditions are those of a progressive unit.

*Apply in first instance to:*

**Group Technologist,  
BOVRIL GROUP RESEARCH LABORATORIES,  
148/166 Old Street, London, E.C.1.**

(367)

**UNIVERSITY OF LIVERPOOL**

**BIOCHEMIST OR VETERINARY  
PATHOLOGIST**

Applications are invited for the post of Research Assistant in the Immunology Cancer Research Unit. Postgraduate research experience and/or higher degree desirable, but not essential. Experience in immunological techniques, protein and enzyme chemistry and/or tumour transplantation in pure strain animals an advantage, but not essential.

The successful candidate will be a member of a team researching into fundamental immunological aspects of cancer in animals and man. Excellent research opportunities in well equipped new laboratories. Salary range £1,100 to £1,500 per annum (plus F.S.S.U.) according to qualifications and experience.

Applications, with curriculum vitae, and names of three referees, to the Registrar, University of Liverpool, Liverpool 3. Please quote Ref.: RV/100/N.

(405)

**UNIVERSITY OF EXETER**  
**DEPARTMENT OF CHEMISTRY**

Applications are invited for a Research Assistantship in Chemistry, tenable for one year from October 1, 1967, for work on the synthesis of a naturally occurring polypeptide under the direction of Professor H. N. Rydon. Applicants should have a Ph.D. degree or equivalent and experience in peptide synthesis. The salary will be £1,200 per annum with F.S.S.U. benefits.

Applications (three copies), including the names of two referees, should reach the Secretary of the University, Northcote House, The Queen's Drive, Exeter, by August 14, 1967.

(384)

**UNIVERSITY OF BRISTOL**

Applications are invited for the post of LECTURER or ASSISTANT LECTURER in APPLIED MATHEMATICS within the Department of Mathematics tenable from October 1, 1967, or as soon after this date as possible. Salary scales: Lecturer, £1,470 to £2,630; Assistant Lecturer, £1,105 to £1,340 per annum with superannuation benefits.

Further particulars may be obtained from the Registrar, the University, Senate House, Bristol, 2, to whom applications should be sent by August 31, 1967.

(316)

## NEW DRUG RESEARCH

Have you had Experience  
or are you interested in any  
of these topics?

### SYNTHESIS

*Amino Acids  
Peptides  
Heterocyclics  
Sulphur Chemistry*

### ANALYSIS

*Analysis of Drugs  
Autoanalytical Techniques  
Elemental Analysis  
Chromatographic Techniques*

### BIOLOGICAL EVALUATION

*Bioassay Techniques  
Toxicology and Pharmacology of Drugs  
Histology*

**OUR AIMS:** We are interested in synthesising new compounds that might be usefully employed in the control and correction of metabolic disorders.

**OUR NEEDS:** An expansion of our research activities has created several vacancies for *organic chemists and analysts, biologists, physiologists, and pharmacologists*, within the new research laboratories of Horlicks Pharmaceuticals Limited.

**OUR LOCATION:** The laboratories are situated in the delightful countryside of rural Berkshire adjacent to Windsor Great Park. They offer facilities and a working environment that are compatible with creative research work.

**WE WELCOME:** Application for these posts both from graduates with 1-2 years' experience and those recently qualified with a first or second-class Honours. Applicants are invited to write to:

**The Personnel Manager,  
Horlicks Pharmaceuticals Limited,  
Orchard Lea, Winkfield, Windsor,  
Berkshire.  
Telephone Number: Winkfield Row 2963**

(301)

## Algologist/ Plant Physiologist

to study primary production and factors limiting the production of phyto plankton at Loch Leven as part of an International Biological Programme study.

**Qualifications:** a first class or good second class honours degree in Botany with special interest in primary production or plant physiology. Candidates with a degree in biochemistry or an allied subject with interest in or knowledge of fresh water algae will also be considered.

**Location:** the successful applicant will be based at Edinburgh but may spend part of his time at the Freshwater Fisheries Laboratory, Pitlochry.

**Starting salary:** according to qualifications £926 to £1,744 rising to £2,155.

Further information and application forms, to be returned by August 18, may be obtained from the Nature Conservancy, 12 Hope Terrace, Edinburgh 9.

(358)

### NEW ZEALAND

#### MARINE DEPARTMENT

Applications are invited for the under-mentioned vacancies:

Vacancy B 13/13/17/2512

#### SCIENTIFIC OFFICERS

Fisheries Research Division

Fisheries Research Division of the Marine Department require two Scientific Officers for research on Mollusca and Demersal Fish.

**Salary:** Appointments will be made in the range \$NZ2,635 (for Honours \$NZ2,730) to \$NZ3,140 for a new qualified Ph.D. and up to \$NZ5,330 for suitably experienced scientists.

**Qualifications desired:** Applicants should have a degree with 1 or 2A honours in Zoology.

**Passages:** Fares for appointee and his wife and family, if married, will be paid.

**Incidental expenses:** Up to \$NZ70 for a single man and \$NZ200 for a married man can be claimed to cover the cost of taking personal effects to New Zealand.

Application forms and general information are available from the High Commissioner for New Zealand, New Zealand House, Haymarket, London, S.W.1, to whom applications will close on August 18, 1967.

Please quote reference B 13/13/17/2512 when inquiring. (410)

### UNIVERSITY OF BRISTOL

#### STATISTICIAN

Honours graduate in Mathematics, with qualifications in Statistics and an interest in biological problems, is required by the Department of Agriculture and Horticulture, Long Ashton Research Station, for the post of Head of the Statistics Section. Appointment as Scientific Officer or Senior Scientific Officer, according to qualifications and experience.

Further particulars from: The Registrar, Senate House, Bristol 2, to whom applications should be sent by the end of August. (376)

### HACKNEY & QUEEN ELIZABETH GROUP HOSPITAL MANAGEMENT

#### COMMITTEE

QUEEN ELIZABETH HOSPITAL  
FOR CHILDREN,

HACKNEY ROAD, LONDON, E.2  
(INSTITUTE OF CHILD HEALTH)

Applications are invited from graduates with good honours degree in chemistry or equivalent qualifications to assist in research on mucopolysaccharides in disease. The post is for three years and suitable for those wishing to study for a higher degree. Salary according to experience and qualifications on the scale to £963 to £1,658 per annum plus London Weighting allowance.

Apply immediately for application form obtainable from Group Secretary, Administrative Offices, Hackney Hospital, London, E.9. (427)

### MACAULAY INSTITUTE FOR SOIL RESEARCH

Applications are invited from graduates with first- or upper second-class honours in mathematics with statistics, or a Diploma in Statistics, for a vacancy in the Statistics Section. The duties are mainly concerned with the design and analysis of field and laboratory experiments, providing a statistical and data processing service. There is access to electronic computers. The appointment will be made in the Scientific Officer Grade, starting salary within the range £926 to £1,574 per annum, according to age, qualifications and experience. Superannuation under F.S.S.U.

Forms of application may be obtained from the Secretary, The Macaulay Institute for Soil Research, Craigiebuckler, Aberdeen, AB9 2QJ, to whom they should be returned before August 28, 1967. (425)

## GROWTH LIKE TOPSY'S

THE Medical Research Council is accustomed to ask a lot of its wellwishers. Its annual report is traditionally one of the most laconic of public documents, more an advertisement of recent achievements than an explanation of how and why money has been spent in particular ways. The latest instalment (see page 570) is no exception to this rule, even though on this occasion the council has made a passable attempt to explain how certain items in its budget have been increased as a result of circumstances outside its own control. But nothing in the 317 pages of text which make up the annual report for the year ending last March could be mistaken for a proof that the council is possessed of a coherent strategy for medical research. No doubt there are many among the members of the council who will point out that it has managed well enough without a strategy for 54 years, and that it need not at this late stage embrace the doctrines of conscious decision making which younger organizations find helpful and even essential. But the truth is quite the opposite. If the council carries on like this, it could find itself in serious trouble before many years have passed.

That said, it is only fair to recognize that the council's own smugness probably derives from its quite extraordinary record of successes in the past 20 years. It has quite rigorously backed good people, not theoretical schemes. One result is that it now has on its payroll a distinguished company of people whose output of original research is an important part of all the science practised in Britain. And it will be a long time before people forget that it was the council which had the foresight to provide funds and an assured future for what is now the Laboratory of Molecular Biology at a time when the University of Cambridge was discredibly indifferent to an urgent need and a splendid opportunity. But this is only one example of what the council has done to provide a setting in which talented people can function efficiently. The council, devoted to the principle of direct labour as the saying goes, has more than 3,000 people on its books of whom 900 are scientists and most of whom are employed in the council's own laboratories and in the 77 research units scattered through the country. For all the scale of this operation, however, the council has hardly ever put a foot wrong—the proposed Clinical Research Centre may yet prove one of the exceptions. So who can blame the council if at times it seems like a kleptomaniac baseball promoter anxious to see that every player of distinction is properly signed up? Who can complain at the successful pursuit of excellence?

The first thing to be said is that the criteria by which the council determines its own success may not be the

ones it should use. The policy of supporting academic research by the direct employment of research units which often work separately from the universities, and which are sometimes not even loosely connected with them, is at least open to question. And since the most immediate and tangible benefit of academic research is usually the benefit it provides for university teaching, there is something in the view that much of what the council has spent on its research units could have brought greater if less spectacular benefits if it had been spent on the direct support of university research. As things are, there is some evidence that the council's policy of supporting research units so handsomely draws talented academics away from teaching. Nobody can be cheerful about the gibe that Dr F. H. C. Crick, an MRC employee among other things, lectures more often in Cambridge, Massachusetts, than in Cambridge, England, even if the University of Cambridge is more to blame for that than the MRC. But then there are other problems or potential problems as well. Thus MRC staffs do not have the same freedom as their academic colleagues. Although directors of research units are usually far-sighted enough to interpret the regulations liberally, their restriction is open to abuse.

For the council as a whole, however, the most serious problem occasioned by the existence of the research units is that the budget as a whole is made inflexible. After all, setting up a unit implies a long term commitment extending beyond the usual span of a research grant. It is no wonder that the council this year finds itself confessing that of its total expenditure of more than £12 million last year, forward commitments were such that only £900,000 could be reckoned "freely deployable". It is only natural to wonder what plight the council would have been in if the Council for Scientific Policy had been unable to win a handsome increase of expenditure for the research councils in the financial year now ended. Would the council have gone round sacking people, or would it have had to put up the shutters in the informal financing of research? And what will happen if the Treasury turns nasty this year, or next? Although there is nothing in the annual report to explain what has been happening, the council's expenditure on informal research grants in university departments is fortunately growing more quickly than any other item in its budget, but it would be good to know whether the council is really guarding against what seems to be an obvious danger.

Because these questions about the council's conduct of its operations suggest themselves naturally, it does not follow that there are no answers to be made. Indeed, it is conceivable that everything has been thought out properly in advance. At this stage the

only complaint that can be made is that the council keeps its reasoning to itself. The most immediate hazard is that in the process wrongheaded policies may go unrecognized, even by the council. But there is possibly a greater cause of loss than that. Because the council occupies a pre-eminent position in the pattern of research in Britain, it is natural to look to it not merely for the conduct of research but for a lead in the evolution of research policy. If the council is ever to shake off its reputation for gifted—or perhaps just lucky—empiricism, it will have to cultivate the skill of stating its objectives publicly.

## FUSION BY HALVES

THE decision that the scale of operations at the Culham Laboratory should be cut in half is painful for everybody concerned. Even Mr Wedgwood Benn had no relish for the task of cutting down the budget, which is plain enough from what he had to say in the House of Commons on July 26. But the sense of regret which may haunt the Minister of Technology will be nothing compared with the regret at the laboratory itself. People will start looking around for jobs elsewhere and will quite understandably ask why it is they who should be the victims of such cruel circumstances.

Unfortunately, of course, there is very little doubt that the decision now taken has been necessary. For several years now the work at Culham, as at the other thermonuclear laboratories scattered around the world, has been directed at a receding target. It is a long time since people used to make calculations about the detailed operating characteristics of thermonuclear power stations—the optimum output of electricity, for example, or the cost of the concrete shielding necessary to keep the installations safe. Instead, thermonuclear research has become a synonym for the careful study of instabilities in electrical discharges through highly ionized plasmas. Those engaged on it have been cheered up when from time to time it has become clear that their work could be useful in other fields—in astrophysics, for example. Although it would be foolish now to say that the commercial exploitation of thermonuclear power is not feasible—indeed, the opposite is probably the truth—those who work in fusion have been forced to take the long view. This is one reason why they have been quick to point out that the experiments with the large pieces of equipment which they use may bring much more immediate benefits in electrical engineering, for thermonuclear equipment is a notorious consumer of high density current. The trouble here is that it is not possible, in Britain at least, to justify the cost of research programmes by the putative value of the spin-off they may provide. In the circumstances there is no doubt that Culham has grown too big.

But if not fusion why not something else? In other words, why shouldn't Culham take a leaf out of the Harwell book and attempt to diversify its activities?

Reading between the lines of Mr Benn's statement in the House of Commons, the ministry is not keen to encourage this possibility. That, too, is also right. For one thing, there is no assurance that Culham would be any more successful at finding self-financing work to do than the other public laboratories now touting for industrial contracts. Evidently there are limits to the extent to which industrial research can be subcontracted. But it is also important to acknowledge that it would be intolerable if the long-term pattern of applied research in Britain were determined by the historical accidents of where laboratories were established in the forties and fifties. Indeed, long-term economic interests may even require that laboratories should be regarded as expendable. Certainly they are much less durable capital assets than, say, steel works. The cost of building them and equipping them is often less than the cost of running them for five or ten years. In other words, if the present scale of operations at Culham is really too lavish, there is no point in supporting it at an artificial level. To let things run down to half over five years seems sensible in the circumstances.

Whether it is wise to let Culham continue as a dependant of the Atomic Energy Authority is another matter. In previous years there seems no doubt that Culham has profited enormously from rubbing shoulders with those engaged on reactor design at Harwell and elsewhere. For some years to come, however, there will be much less profit to be derived that way. A question which needs asking is what setting will best allow a £2 million a year laboratory like Culham to keep going productively. There is a strong case for thinking that the laboratory would be better off under the Science Research Council than as a continuing dependant of the AEA. (Another less satisfactory possibility would be an autonomous laboratory within the Ministry of Technology.) For one thing, there would then be a chance that it could flourish as the magnet laboratory on which the SRC seems to have set its heart. It might also then be able to contribute more effectively than at present to the development of university interests in plasma physics. As things are, the universities do not participate in the design of the biggest pieces of equipment. And in the long run, of course, it would be possible to arrange that the scale of expenditure at Culham could be determined by a sensible matching against other demands for funds for long-term research.

There remains the question of whether the experience with the Culham laboratory will persuade scientists that working for the Government is as hazardous as working for industry. However much advantage may be taken of what is called natural wastage at the laboratory, the chances are high that many people will find themselves moving to other places against their wishes, possibly because opportunities of promotion are not easily offered. It would be sensible if the Government would recognize that this is as much a social problem as the difficulty caused in coal fields throughout the country by the running down of fuel production. In other words, the Government has a

duty to ensure that people whose jobs come to an end or whose prospects are unreasonably dimmed must be given some kind of help to find other outlets for their energies. No doubt there will be some talk of compensation payments. No doubt attempts will be made to fit people in elsewhere within government establishments. But it would be better in the long run, and a good precedent as well, if the Government were to recognize that what the circumstances require is a thorough-going programme of retraining and resettlement backed up by generous schemes for helping people move from place to place. One of the ironies of the two decades since the war is the growth of the assumption that scientists working in some narrow field cannot be expected to transfer their interests to some other. It seems to have been forgotten that during the Second World War every other biologist was trained to be a radar engineer almost overnight. If the country is really short of talent, and if the Ministry of Technology is anxious somehow to increase the effectiveness of what there is, it should put its energies into making full use of the people who will no longer be fully occupied at Culham.

## SPEAKING FOR UNIVERSITIES

THERE is something entirely appropriate about the election of the new chairman of the Committee of Vice-Chancellors and, in the same week, the announcement that the Department of Education and Science will, after all, assume direct responsibility for seeing that universities spend public money in a manner which is seemly but as yet undefined (see page 576). The universities have never been as much in need of somebody who can act on behalf of them all. With one thing and another it has been a bad year for the universities. For one thing, it is becoming ominously to seem that the first bite at the Robbins cherry may also be the last. Gone already is the heady talk of how the university system might grow and grow so as to provide a substantial part of the adult education on which such hopes as may survive for British economic prosperity must rest. The gloom which has been accentuated by the tactless handling of the equipment grants by the University Grants Committee may lift when the funds for the five years from 1968 are announced later in the year, but nobody can be cheerful at this stage. And then there is the galling incident of the Government's decision to increase fees for university students from overseas without properly consulting the universities. Yet the universities themselves have done very little to face up to the problems which confront them. Such talk as there may have been of more efficient operation seems to have been largely ineffectual. The Standing Conference on University Entrance will probably come out with more liberal rules for admission in the next few months, but the universities as a whole have done

little more than Oxford after Franks to protect themselves from criticism.

This is why the new chairman of the Committee of Vice-Chancellors can play a decisive role. It has been plain for the past five years that the UGC is less and less effective as a buffer between the universities and the Government. That this should have happened is inevitable. The growth of the scale on which the universities are supported by public funds is less important than the now open abandonment of the whole convention that universities should be protected from the knowledge that they are living on taxpayers' money. Indeed, it is no longer possible for a government to allow that universities acting for themselves should make important decisions affecting public policy. And it is, of course, entirely sensible that the Government should have the last word about questions such as the proportion of the British GNP to be consumed by higher education. A good many in the universities will agree with that. Yet the universities must be able to retain freedom over academic policy and self-respect as well. Even if the UGC can keep for itself something more than the role of being Sir Herbert Andrew's auditing department, there is now no chance that a body of civil servants like the UGC can set itself up as a means of keeping an effective dialogue with the Government on university policy and, when necessary, as over fees for overseas students, to defy the Government. For a long time it has been obvious that only the Committee of Vice-Chancellors could fill that role.

But what needs to be done? The most immediate task which Dr Christopherson should undertake is to let it be known that the Committee of Vice-Chancellors is not some kind of quasi-judicial body, a pillar of the establishment, but an institution which must be reckoned a political force. For too long the committee has sought to win respect by making itself almost inaudible on matters of public policy. The trouble, of course, is that if it is to carry university opinion, the committee must function publicly, making statements, publishing newsletters and sometimes even taking steps to improve its standing with the non-academic world. If on some occasion it finds that the Government has not consulted it on important issues of principle, it should feel free and strong enough to take unilateral action on its own account. (A public appeal for funds to make up overseas fees would have been an interesting exercise.) And then, of course, the committee must somehow capture the respect and the loyalty of the separate universities, so that it can act quickly on their collective behalf. This in turn will imply that universities must delegate some of their freedom of action to the committee and, lower down the hierarchy, that university departments must give up some of their present autonomy for the greater good. How far things can go in these directions, only time will tell. But clearly one of the most obvious needs is that the chairman of the committee should command respect. Fortunately, Dr Christopherson is the sort of man who will appreciate what needs to be done.

## NEWS AND VIEWS

### Cuts at Culham

By deciding to reduce by half the expenditure on thermonuclear fusion research at Culham Laboratory, the Atomic Energy Authority has risked offending its friends without much pleasing its enemies. The work of the laboratory has been devoted to the production of a commercial reactor using thermonuclear fusion reactions, instead of the fission reactions used in current reactors. Although a committee set up by the authority is believed to have recommended that the laboratory be shut altogether, the authority finally decided that expenditure should be reduced by 10 per cent annually for five years, at the end of which time there should be a review of the situation. Although the problems of plasma containment are particularly elegant and interesting, nobody would deny that they are difficult in the extreme, and the axe has been hanging over Culham for several months.

The cost of the laboratory last year was about £4 million. It has been higher than this; in 1964-65 it cost £5 million to run. It is not a particularly old laboratory—construction did not begin until 1960. The staff of 800 includes 190 qualified people and a number of visitors from abroad on short or long term contracts. Although the great majority of the effort has been directed at controlling artificial plasmas, the laboratory has also allowed itself to be involved in the study of natural plasmas by space soundings. Recently it won the contract to supply the telescope for the ESRO astronomical satellite. Despite doubts about the satellite project, which will not get the final go-ahead for some months, there does not seem much room for economy in this side of the work. Since only a quarter of the budget this year is intended for capital expenditure, most of the cuts will have to be made on current expenditure, which is likely to mean reductions in staff. Despite this, the authority hopes that there will be no formal redundancies and that the staff can be reduced by natural wastage; there is also an unexplained optimism that the wastage will not be directed overseas.

At Culham itself the staff are naturally upset by the decision, although it was not unexpected. Much of the rancour is directed at the cloak of secrecy with which the AEA has surrounded the decision, and the fact that only two years after opening a laboratory which cost £6 million to build, the AEA can close half of it without even explaining publicly the reasons for the decision. Mr Benn's explanations in the House of Commons cut no ice at Culham, and his rejection of suggestions that the programme at Culham was inflated by the staff there have merely served to confirm the feeling that the authority alone is responsible for the mess. There is also doubt about what the half of the laboratory that will be left will be used for; above all the staff at Culham feel the need for something challenging to do. Unless the authority or the minister can produce ideas soon, the argument runs, the remarkable esprit de corps which has been a feature of Culham may be lost.

### New Broom for ESRO

It can be stated with confidence that the election of a theoretician, Professor Hermann Bondi, as director-general of ESRO does not imply a decision to abandon experimental work. This would be to belittle both ESRO's power of survival and Professor Bondi's experience of the hardware of space research. Professor Bondi, 48 and a familiar figure in astronomy since he graduated from Trinity College, Cambridge, in 1940, is Professor of Mathematics at King's College, London. He was elected director-general at a meeting of the council of ESRO on July 27, and succeeds Professor Pierre Auger, who has been director-general since ESRO started. The appointment is for three years, and after an initial period when Professor Bondi will be arranging for his commitments at King's College to be taken over, he will be working full-time for ESRO.

ESRO has some tricky decisions to make during the next year—whether, for instance, to remain a coherent entity or to merge with ELDO. The ambitious astronomical satellite which ESRO hopes to launch still awaits final approval, although contracts have been provisionally placed, one with the Culham laboratory of the AEA. Professor Bondi is familiar with the mechanism of decision-making—he is chairman of the Astronomy Policy and Grants Committee of the SRC, and a member of the Astronomy, Space and Radio Board. He is also chairman of the British National Committee for Astronomy. ESRO is doubtless already bracing itself for the shock of his arrival—cynics have been heard to comment that whether or not Professor Bondi needs ESRO, ESRO certainly needs him.

### Effortless Progress

THE Medical Research Council has survived another unruffled year, to judge by its annual report (HMSO, £1 6s. 6d.). Of all the research councils, the MRC is surely the most machine-like. This year even a new constitution, which provides for an increase in membership of the council from 12 to 16, and for the Secretary of State for Education and Science to take over the responsibilities of the Committee of Privy Council for Medical Research, has failed to put a spanner in the works.

For the past few years the MRC has been batting on a gentle wicket. Grants have been steadily rising at a rate of around 20 per cent per year (11 per cent in real terms, the council points out), and last year the council spent £11.8 million, more than double the figure for 1962-63. The council now supports no less than 77 units, the National Institute for Medical Research at Mill Hill, and research at universities and hospitals. Short term grants, though, are taking an increasing share of the budget—17 per cent, or £2.2 million this year.

The report for 1966-67 includes a 60 page section describing progress in some of the fields of research which the council supports. These well written and useful reviews include descriptions of the work which has shown that men with two Y chromosomes may be predisposed to crime. Although XYY males are very rare indeed in the population at large, a survey in a special security hospital has shown 9 such men in a sample of 315 (Jacobs *et al.*, *Nature*, **208**, 1351; 1965).

Other reviews cover the scientific aspects of ageing, the control of protein synthesis in living cells, and pulmonary hypersensitivity caused by organic dusts. Two main types of allergic reaction have been distinguished, called Type I and Type III, and they may be present in lung disease either separately or together. Type I allergy is induced by exposure to everyday dust, and as many as 10 per cent of the population are at risk, but it leaves no tissue damage. Type III is induced by constant exposure to dusts, and the reaction, which involves tissue damage, develops more slowly. Farmers inhaling the dust from damp and mouldy hay, pigeon fanciers and granary and sugarcane workers are all found to suffer from this disease. Tests now make it possible to diagnose these different diseases, and farmer's lung is already registered as an industrial disease.

## Science in Belgium

THE Belgian National Council for Scientific Policy has just published its report for 1967. It fears that the fact that Belgium lags behind other European states in science and technology may be prejudicial to her economic integration into Europe. Belgium cannot reasonably expect to compare in scientific output with the greater European countries; this would require a disproportionate percentage of the gross national product to be spent on research. It is the aim of the council to bring Belgium up to the level of the smaller European countries, such as Sweden or Holland. To this end, the council recommends that by 1972 expenditure on science should have risen to 2.15 per cent of the GNP. Government spending must rise from 8.2 million francs in 1966 to 17.8 million in 1972, when it is expected to comprise 3.42 per cent of the budget.

The council has appointed commissions to prepare the budgets for research establishments and deal with the expansion of the university system, and to study the means by which research programmes are directed and financed. A good deal of administrative reorganization will be necessary, especially that concerned with technological as opposed to basic research. A greater knowledge of the research facilities and trends in Belgian industry is needed, and the council has already begun collecting this kind of information.

An interesting proposal is that the council should recommend the salaries of research workers attached to projects subsidized by the State.

## New Man for Universities

THE fuss about university accountability has already revealed one unexpected fact. The Committee of Vice-Chancellors and Principals, a conspicuously modest and self-effacing body which represents universities at times like these—and tends to disappear in the interim—has a new chairman. He is Dr D. G. Christopherson, Vice-Chancellor and Warden of the University of Durham. He took over as chairman early in July, and although nominally elected for one year, it will be breaking all the traditions of a particularly traditional organization if he is not re-elected on the nod for a further two terms. This was what happened to his predecessor, Sir Charles Wilson.

Dr Christopherson has experience in a number of posts, and, perhaps fortunately in his new job, of a great variety of universities. After graduating at University College, Oxford, he was Henry Fellow at Harvard University in 1938, and a scientific officer in the Ministry of Home Security during the war. Since the war he has been a demonstrator and lecturer at Cambridge, professor of mechanical engineering at Leeds and of applied science at Imperial College, before going to the University of Durham in 1960. In 1961 he was chairman of the academic planning board for the University of Kent, and has been a member of the Science Research Council since 1965. In the present atmosphere of uncertainty, universities may be glad that there is a new man at the helm, although Dr Christopherson might well have preferred to have been pitched in at a less controversial moment.

## Golden Gates

CONSIDERING California's wealth in laboratories and scientific institutes, it is not surprising to learn that she receives the lion's share of American federal funds for research and development. In fact, California received 31.7 per cent of the \$14,400 million spent in 1965; the second largest share went to New York with nearly 9 per cent; Maryland received 6.1 per cent; Massachusetts and Texas each received 5.1 per cent. These figures come from the National Science Foundation's report on the "Geographical Distribution of Federal Funds for Research and Development".

Between 1963 and 1965, Federal spending on research and development rose by 17 per cent, from \$12,250 million to \$14,400 million. In this period, fourteen States showed a decrease in spending and thirty-seven an increase in spending. The change in distribution was largely caused by the phasing out of the Gemini programme and the building up of the Apollo programme, and the completion by the Air Force of several large weapon systems.

On a prime contract basis, 63 per cent of the Federal research and development spending went to industry, 21 per cent to Government laboratories, 8 per cent to educational institutions, 4 per cent to federal contract research centres administered by educational institutions, and 4 per cent to other non-profit-making institutions. As might be expected, a large proportion of the Government laboratories are in or around Washington, and so three States—Maryland, the District of Columbia, and Virginia—received almost a third of the spending on Government laboratories. California received a sixth of the spending in this sector.

The universities have had a greater increase in their share of federal research and development spending than either industry or the Government laboratories; in 1963 they received \$851 million and in 1965 they received \$1,200 million. Although the universities receive only 8 per cent of the total federal research and development spending, their influence is far more extensive because they train scientific manpower and provide consulting services and technical expertise to both industry and Government. New York, California and Massachusetts received 37 per cent of this educational institution spending, thanks to the influence of seven universities: Columbia and Cornell in New York, California (Los Angeles and Berkeley) and Stanford in California; and MIT and Harvard in Massachusetts.

## Concord Still Going Up

THE Public Accounts Committee of the House of Commons is in particularly good form at the moment. Not content with its recent report on Bristol-Siddeley engine contracts, it has now published a report detailing other examples of overcharging. Almost inevitably, one of the things which the report reveals is that the cost of Concord has gone up again, despite the fact that the last estimate of £500 million contained no less than £50 million for "contingencies". The extra figure this time is £28 million, which the Ministry of Technology had apparently forgotten to include—it represents an allowance for spending at the ministry's own laboratories. The committee also criticizes the agreement between France and Britain on intramural expenses, which was "ambiguous".

The committee also suggests that other contracts have been agreed at prices favourable to the companies involved. In particular, the price of Buccaneer aircraft was too high, and the committee notes that Hawker-Siddeley have now agreed to repay any profits over the figure of 17.5 per cent on costs; it does not, however, reveal how much this is.

## Organizing Aid

WHAT is the best way of distributing aid given for the general economic development of the poorer countries of the world? The problem of a strategy for aid-giving is dealt with by a recent publication of the Overseas Development Institute, called *Pledged to Development*, and written by John White, a research member of the Institute.

Previous studies by the institute have revealed wide divergences in the motivation, administration and financial characteristics of the different aid programmes, as well as in the approach of the aid-giving countries to the fundamental questions of the nature of economic aid. A further study of a single aid-receiving country—Uganda—showed that these divergences can give rise to practical problems. Not only is there a loss in efficiency when donors are dealing with different problems in the same undeveloped country—more fundamentally, a successful aid programme must deal with the whole economy, over a long period of time. Since very few donors are prepared to take on this kind of project, even for a small underdeveloped country, consortia or consultative groups of donors must be formed. In 1958 the Indian Consortium was formed, and in the next few years similar groups were formed for Pakistan, Greece and Turkey. For a number of other countries consultative groups were set up, which differ from consortia in that the countries contributing are asked to make no specific financial pledge to the development programme.

It is with these groups and the strategy of aid that the book deals. The word "strategy" is one used by the author. It reflects his view that future operations of the group will require more than co-operation between the various members; a joint command is needed, delegating authority to the countries concerned. For this an international organization with some degree of operational autonomy is required.

This point, and other questions of the mechanism of the group, are discussed in the light of two earlier chapters which are case histories of the Pakistan

Consortium and the Turkish Consortium, respectively the most and the least successful of the consortia so far formed. Mr White's conclusions as to the nature of the groups and how they should work differ in some respects to the views of the World Bank, the agency responsible for the largest number of aid groups.

As he points out, the original aim of the aid-giving countries in the late 1950s was to raise the standard of living of all the poorer parts of the world to a tolerable level. For various reasons this soon declined into a situation in which aid was given to only a few countries. Perhaps the groups envisaged by Mr White will be more successful in dealing with the critically important problem of world hunger.

## More for NRDC

THE National Research Development Corporation has nearly spent the £25 million that it has been entitled to borrow from the Ministry of Technology. Because of this, the Minister, Mr Anthony Wedgwood Benn, will introduce legislation to increase the limit of the advances that may be made by the ministry to the corporation. The ceiling of the corporation's borrowing powers was last raised, in June 1965, from £10 million to £25 million. Mr Benn's legislation, which will double the amount to £50 million, can be expected to pass through Parliament early next year.

Though the corporation's income from licence receipts has been increasing consistently since 1962, it will continue to depend on loans from the ministry for a long time. The loan of 1966 alone far exceeded the earnings of the corporation over the previous 31 months. But increasing the power to borrow is the clearest way to solvency for the corporation. Backing research projects for profit is, like any other stochastic process, more likely to be successful the greater the scale of operations.

## Instruments under Pressure

SUPERFICIALLY, the annual report of the Scientific Instrument Manufacturers' Association for 1966-67 makes moderately happy reading—overall production is up by 4.7 per cent, above the chancellor's target growth rate of 3 per cent, and export sales are up by 9.1 per cent. When, however, the figures are compared with those for the previous five years, 1960-65, things do not look so bright—in that period there was an annual increase in production of 12 per cent. This setback can be attributed mainly to the "freeze", because production in the first half of 1966 rose by 11 per cent compared with 1965, while in the third quarter it rose by only 3 per cent and in the last quarter it fell by 5 per cent.

Although exports were up 9.1 per cent, imports were also up, and by a greater percentage. At the present moment, there is a favourable balance of payments in this industry, but unless imports slow down or exports speed up, imports can be expected to overtake exports within the next four or five years. The present drop in overall world trade and the tariff cuts agreed in the Kennedy Round which will slowly come into force over the next five years will do nothing to help the industry's position.

The scientific instrument industry in Britain is well protected behind some relatively high tariff barriers,

averaging about 30 per cent; these will be cut by half, to about 15 per cent. On the export side, tariff barriers are also being cut: the EEC tariffs drop from an average of about 15 per cent to 10 per cent; Japan's tariffs drop from an average of 15 per cent to 7.5 per cent; and almost all USA tariffs are being cut by half. This will make British products more competitive with those of the home country but it will also have some side effects. In EFTA, for instance, we can export instruments to Sweden free of charge to compete with those of Sweden, but the tariff cuts mean that instruments from outside EFTA gain competitiveness while ours remain the same. Similar arguments apply to Commonwealth countries, where Commonwealth preference has aided Britain in the past.

Some idea of the effect of the tariff cuts can be gained by considering one particular instrument such as a balance with a sensitivity of five centigrams or better: to import one into Britain a tariff of 33½ per cent has to be paid, and this will now drop to 17 per cent; the Japanese tariff drops from 15 to 7.5 per cent; the USA tariff from 25 to 12.5 per cent; the EEC tariff from 18 to 9 per cent; and the Swedish tariff for balances from outside EFTA from 10 to 5 per cent. The figures for a thermometer are about the same: Britain's tariff drops from 25 to 12 per cent; Japan's from 15 to 7.5 per cent; the USA tariff on clinical thermometers remains the same at 42.5 per cent, but drops from 42.5 to 21 per cent on all other thermometers; the EEC tariff drops from 17 to 12 per cent; and the Swedish tariff for all thermometers from outside EFTA drops from 10 to 5 per cent.

The report states that not all segments of the industry were equally affected by the "freeze". Optical instruments, which slumped badly in 1965, recorded increased production throughout the year and almost regained their 1964 position. Electrical and electronic instruments made a marked improvement in their export figures, but industrial process measuring and control instruments were badly affected and production for export dropped by 21 per cent. The production of measuring and scientific instruments showed an increase of only 3 per cent.

## Patent Law Reform

THE Membership of the Board of Trade Departmental Committee was announced recently by the President of the Board, Mr Douglas Jay. The chairman will be Mr Maurice Banks, who is at present chairman of the Ministry of Technology's Advisory Council on Calibration and Measurement. The other members will be Mr P. J. Stuart Bevan (Deputy Chairman), Mr J. C. Duckworth, Mr G. D. Everington, Mr D. Gladwin, Mr A. W. Mallinson, Mr H. R. Mathys, Mr C. W. Morle, Mr A. Silberston and Professor F. C. Williams. The committee will act with the assistance of the Comptroller-General of the Patent Office.

The formation of the committee comes at a time when revision of patents and patent law is being undertaken in both Europe and America. Indeed, one of the tasks of the committee will be to facilitate the interchange of patent information along the lines agreed by the recent Council of Europe Convention. A standing committee, headed by Mr Mathys, will advise the board on these matters.

What hampers the passage of patent information is, in part, the fact that the establishment of patents involves legal and other problems peculiar to particular countries. In America, the Sherwin Committee (many of whose recommendations are embodied in the Patent Bill now before Congress) suggested the setting up of information centres, in which interlinked computers stored patent information in a standardized system. Such ideas may come to fruition slowly. In the meantime, there may be a case for transferring responsibility for patents from the Board of Trade to the Ministry of Technology. This would be to recognize that patents are as much pieces of scientific information as commercial assets.

## All Done by Numbers

ANY effort to take the guesswork out of engineering is to be commended. To this end, the Institution of Chemical Engineers and the Institution of Mechanical Engineers, with financial backing from the Ministry of Technology, are producing a series of Design Data Memoranda for publication. The first four—approximate data on the viscosity of some common liquids; heat transfer in tubes; thermal conductivity of liquid alcohols; and thermal conductivity of water substances—were launched at a press conference on Tuesday, July 25.

Data sheets were originally pioneered by the Royal Aeronautical Society twenty-six years ago. The Fielden Committee stated in 1963 that they were a way of improving standards of engineering design, and proposed that the work be extended to other fields, and that other professional engineering institutions should participate. It is hoped that the issue of up to date engineering design data will aid engineers in design problem and will save industry from maintaining costly non-specialist data.

## Anniversary Conference

FORTY years ago this year the first announcements of the diffraction of electrons by crystals were made, in letters to *Nature* by C. Davisson and L. H. Germer, then of Bell Telephone Laboratories, New York, and by G. P. Thomson and A. Reid, of Aberdeen University (*Nature*, 119, 558 and 890; 1927). In commemoration of this anniversary, a conference was held last month at Imperial College, London, under the auspices of the Institute of Physics and the Physical Society (Electron and Microscopy Analysis Group). The conference was opened by Professor C. C. Butler, F.R.S. The two survivors of the four original discoverers, Sir George Thomson, F.R.S., and Professor Germer, each spoke on the history of electron diffraction. Professor Germer reviewing low energy electron diffraction, a field in which he was particularly active until his recent retirement.

## No Fundamental Length

from a Correspondent in High Energy Physics

A RECENT experiment at the Brookhaven National Laboratory (S. J. Lindenbaum *et al.*, *Phys. Rev. Letters*, 19, 193; 1967) has provided for the first time a critical test of the current concepts of space and time

at really short distances. The conclusion drawn from this experiment is that for distances down to the order of  $10^{-15}$  cm there is no evidence whatsoever for a primitive acausal (in the sense of special relativity) region or fundamental length.

It has been known for some years (R. Oehme, *Phys. Rev.*, **100**, 1503; 1955) that the existence of an acausal region of space time (across which signals might be propagated at velocities exceeding that of light) leads to a failure of forward dispersion relations for elastic scattering. These relations, which are based only on very general theoretical considerations, state that apart from various subtraction constants and kinematical terms the real part of the elastic scattering amplitude (say, for pion-proton scattering) is given by an integral over energy of the total cross section for the process multiplied by well defined functions of this energy. Thus if the real part of the scattering amplitude can be measured (and this is the difficult part) for some simple elastic process where the total cross sections are well known, a critical test of our space-time concepts becomes available.

Lindenbaum and his colleagues have carried out elastic pion-proton scattering experiments in the momentum region 8–26 BeV/c using an impressive array of counter equipment linked directly to computers to provide both permanent record and immediate on-line analysis of data. Although two amplitudes are required to describe this process in general (corresponding to the possibility of reversing the spin of the proton) only one is of significant magnitude at small scattering angles and the experiment is correspondingly performed at angles less than 25 mrad. The real and imaginary parts of this amplitude can be separated by examining in detail the small interference effect (in the differential cross section) between the dominant strong interaction and the much weaker electromagnetic one. It is the very small magnitude of this effect coupled with both theoretical and experimental uncertainties as to form factor and multiple scattering corrections which make this such a hard experiment.

The interference has been found to be destructive for negative pion scattering and constructive when positive pions are used. In the former case the ratio of the real to imaginary parts of the amplitude is almost constant at  $-0.13$  throughout the measured range, and in the latter case rises smoothly from  $-0.22$  at 8 BeV/c to  $-0.14$  at 20 BeV/c. By comparing these results with the measured total cross sections (the authors have also remeasured these, but have not yet published their results) integrated in the dispersion relations, it has been established that good agreement exists at least up to values of 20 BeV/c for the pion momenta.

Experiments which test such basic concepts are quite rare, and ones which combine such powerful techniques in both theory and experiment are rarer still. It is a welcome change in these days of the mass production of resonances to see one of the largest machines used in this thoughtful manner.

## Cytochrome c

from a Correspondent in Molecular Biology

CYTOCHROME *c* is an interesting protein for a number of reasons, not least because it offers an unrivalled opportunity for observing biochemical evolution. Cyto-

chrome *cs* have been isolated from vertebrates, invertebrates, micro-organisms and plants, and through the efforts of E. L. Smith, Margoliash and their associates, the amino-acid sequences of a wide range of these have been determined. The most recent study, by Stevens, Glazer and Smith (*J. Biol. Chem.*, **242**, 2764; 1967), gives the first sequence of a plant cytochrome *c*—that from wheat germ—and therefore represents a particularly interesting addition to the series.

The polypeptide chain consists of 112 residues, compared with 104 for all vertebrate pigments. It differs from the other cytochrome *cs* of known sequence (considering only the first 104 residues) in 35–46 amino-acids, and actually shows fewer differences from the human heart protein than that from a fungus. It is extraordinary to discover that between all the known sequences the number of positions in the chain which remain invariant is now reduced to 35. It is true that in many of the variable positions the substitutions are limited to amino-acids of similar kind, for example, that of one non-polar residue for another, but this is by no means always the case. Only one uninterrupted sequence of more than two residues is present in all cytochrome *cs*, namely, the eleven residues, 70–80. In addition, two of the constant residues are cysteines 14 and 17, which are covalently linked to the haem group, and the two residues now generally supposed to act as ligands for the iron on either side of the haem plane, histidine-18 and methionine-80. All known cytochrome *cs* appear to be capable of interacting with mammalian cytochrome oxidase, and the steric requirements for this recognition process evidently therefore involve only a minority of the residues. One may perhaps speculate that the long invariant sequence is in some manner involved in this aspect of the function.

It is a happy circumstance that at the same time the first report has appeared from Dickerson's laboratory (*J. Biol. Chem.*, **242**, 3015; 1967) of the X-ray structure of horse heart cytochrome *c* at 4 Å resolution. This is sufficient to define many of the structural features of the molecule. Cytochrome *c* appears to possess little or no  $\alpha$ -helix. From the distribution of electron density it appears that the molecule conforms well with the principle that the hydrophobic side chains are packed into the interior of the molecule, while the polar side chains coat the exterior. The two cysteine residues attached to the haem, and one of the ligands, histidine-18, can be identified with certainty. The haem group lies in a long crevice down the long axis of the molecule, with one edge only exposed. The chain appears to be in a largely extended state, and the structure is very different from those of the other haem proteins, myoglobin and haemoglobin.

It is to be hoped that as more details become available it will soon be possible to identify the invariant positions in the chain, which must be supposed necessary to define the structure as that of a functional cytochrome *c*.

## Fungal Morphogenesis

from a Correspondent in Microbiology

ONE of the most exciting challenges of contemporary biology is the interpretation in biochemical terms of morphological change. Studies of biochemical differen-

tiation, as this subject is known, have been notably rewarded where microbial systems have been examined; in particular, the diverse processes of sporulation found in micro-organisms have interested many workers. A convenient approach to the study of sporulation involves the use of metabolic inhibitors which interfere with protein or nucleic acid syntheses. Experiments of this type can provide precise information on the process of induction and define the temporal parameters of the morphogenetic sequence. The investigations of Young and Fitz-James and Aronson exemplify this stratagem and have indicated the major changes in protein and nucleic acid metabolism which occur during endospore formation in *Bacillus*.

In the imperfect fungus *Trichoderma* conidia are light-induced, a fact familiar to mycologists for many years. This fungus has been taken by Galun and Gressel as a model system for analysing the involvement of nucleic acids in morphogenesis. Galun and Gressel observed a minimum growth period of 16 h before this mould was capable of responding to light induction and that conidiation was prevented by fluorouracil (FU) at concentrations which did not inhibit growth (*Science*, **151**, 696; 1966). Subsequently, these workers found that an hour's treatment with FU would completely suppress sporulation up to 7 h after light induction (*Developmental Biol.*, **15**, 575; 1967). Once conidiophore branching was completed, however, after about 11 h, sporulation always proceeded although at a reduced level. This aspect of *Trichoderma* differentiation is very reminiscent of the "point of no return" concept in the water mould *Blastocladiella* and the phase of "spore commitment" in *Bacillus* species.

Suppression of sporulation was reversed by uracil, though the uracil appeared to exert an additive rather than the expected competitive effect on fluorouracil action. Uridine also affected reversal of FU inhibition, but, while the tritium label from uridine appeared both in uridylic and cytidylic acid peaks, the carbon-14 label from the analogue was found only in the uridylic-fluorouridylic acid peaks. Fluorouracil suppresses sporulation by its specific action on RNA and it is noteworthy that indefinite growth can continue with a selective inhibition of this morphogenetic pathway. All species of RNA were shown to contain FU and additionally a new sRNA was eluted from methylated albumin columns between the 4S and 5S species. Pulse labelling with FU or uracil yielded a similar RNA elution profile suggesting that the analogue was incorporated into mRNA. Of a large number of other RNA antimetabolites tested, only 8-azaguanine produced results similar to fluorouracil and induced synthesis of the exotic sRNA species.

At the present time the only substantial conclusion to be drawn from these experiments is that the photo-induced sporulation in *Trichoderma* is RNA mediated. The suppression of this specific morphogenetic sequence could be via FU-sRNA, FU-mRNA, via both, or via yet another mechanism. Extended studies of these fraudulent nucleic acids will doubtless lead to important findings on the molecular control of growth and morphogenesis, and future reports from this group will be awaited with considerable anticipation. In particular, the fact that pre-induced cultures can be partially suppressed by FU encourages the hope that significant data may be forthcoming on the nature of the light induction mechanism.

## Mouse Satellite DNA

from a Correspondent in Cell Biology

DENSITY gradient centrifugation separates mouse nuclear DNA into two components: a major component, about 90 per cent of the total, and a minor component, satellite DNA, with a slightly lower buoyant density. This satellite DNA has some very remarkable properties. It is unusually homogeneous in G+C content (Flamm *et al.*, 1966) and undergoes very rapid renaturation at low DNA concentrations (Walker and MacLaren, 1965). Waring and Britten (*Science*, **154**, 799; 1966) found heat denatured satellite DNA renatures faster than any of the other animal, bacterial and viral DNAs that they examined. It even renatures fifteen times faster than simian virus 40 DNA which only has 6,000 base pairs, so satellite DNA must form a homogeneous population of molecules with a repeated sequence of only about 300-400 base pairs. Waring and Britten suggested each mouse genome probably contains about one million copies of this short sequence.

Flamm, McCallum and Walker at Edinburgh have recently achieved the separation of the two complementary strands of the satellite DNA duplex and report on their properties (*Proc. Nat. Acad. Sci.*, **57**, 1729; 1967). After isolating the satellite DNA from the major component by gradient centrifugation they re-ran the satellite band in a caesium chloride gradient at pH 12.5. At this high pH the DNA duplex is separated into its two strands and these have different buoyant densities. The heavy strand is rich in pyrimidines C+T, and the light strand in the purines A+G. The two strands have complementary base compositions and the renaturation characteristics of equimolar mixtures are very similar to those of native satellite DNA after heat denaturation. Neither heavy nor light strands alone will renature.

Interestingly, although some sequence homologies exist between the total DNAs of mice, rats and guinea-pigs, mouse satellite DNA does not renature with total guinea-pig or rat DNA which includes the satellite DNA of these species. It appears that the nucleotide sequences of satellite DNA are completely species specific.

This work is the first in which the complementary strands of DNA from a higher organism have been isolated and the very fact that this can be done implies that satellite DNA is homogeneous and has only a short base sequence. This does not mean, however, that satellite DNA is of low molecular weight. Flamm and his collaborators have isolated molecules with a molecular weight of 40 million, indicating at least 200 repeating sequences of 300-400 base pairs strung end to end. This makes it highly unlikely that satellite DNA is viral or proviral in origin, for it seems inconceivable that a virus could exist with such a genome. Other properties of mouse satellite DNA, its presence in all the strains of mice and tissues investigated, its association with metaphase chromosomes (Maio and Schildkraut, *J. Mol. Biol.*, **24**, 29; 1967) and its metabolic stability, also argue against a viral origin.

What is the function of satellite DNA? It is unlikely to code for protein and yet it forms 10 per cent of the cell's total DNA. What possible purpose is served by having so many, apparently identical, short sequences within the same genome?

## Parliament in Britain

### University Grants

IN the House of Lords, Baroness Phillips, answering for the Government on university expenditure and government grants, said Parliament had voted £22.5 million for 1967-68 for the purpose of meeting drawings on university furniture and equipment. The UGC, when issuing the initial drawing limits, decided to work within a total of £20 million, keeping £2.5 million in reserve. Universities were invited to submit a claim if they wanted a higher limit, and in the event the claims amounted to £21.5 million over and above the total of the limits notified earlier. The UGC saw no possibility of justifying this increase and had proceeded to distribute the remaining £2.5 million.

She said that it was certainly true that the limit which had been assigned to some universities might prove to be less than they could legitimately claim that they needed and less than they would have drawn if the drawing of grants had been left to take their course as in the past. But it was also true overall that more money was being provided for furniture and equipment than in any year in the past. The UGC was making a careful study of the situation, and particularly that of the comparatively small number of universities where, because of particular circumstances, the impact of drawing units had been particularly hard. (Debate, July 25.)

### Co-operation

IN a debate on Science and Technology (Anglo-European Co-operation), Mr Eric Moonman, M.P. for Billericay, said that for many years science and technology had failed to make the impact in Western Europe which might have been expected. People holding key positions in government and industry had failed to pay science and technology due attention. Decisions had been taken about short- and long-term planning without reference to those sections of Government that were encouraging scientific projects, while in

industry large numbers of companies in Europe felt it undesirable or unnecessary to appoint scientists or technologists to key positions or on boards of executives. As a result, their voice was not heard or was not loud enough. Collaboration among European nations and firms was important, he thought, but needed to be established on a meaningful basis.

Mr Anthony Wedgwood Benn, Minister of Technology, agreed with almost all Mr Moonman had said. The high cost of research made it necessary to establish companies large enough to afford it, and the high cost of marketing made it necessary to have large markets to sustain this research. Britain was handicapped by the fragmentation of firms. Although some of Britain's corporations were of a world size they were operating on too small a scale. It was one of the principal objects of the Ministry of Technology to try to bring about larger units in the British engineering industry. (Debate, July 24.)

### Booms

IN a written answer, Mr Anthony Wedgwood Benn, Minister of Technology, said that the sonic boom heard in the London area on July 17 was not comparable in noise, effect or decibel measurement to that which could be expected from Concord. (Written answer, July 21.)

### Doctors

IN a written reply, Mr K. Robinson, the Minister of Health, said that an interview team of five, headed by the Principal Medical Officer from his department, was being sent to visit the USA and Canada early in the autumn to meet British doctors there and offer them appointments in the hospital service or introductions to general practice or to hospital boards. The project had been publicized in the medical press and a large number of inquiries had already been received from British doctors interested in returning to Britain. (Written answer, July 24.)

## Keeping an Eye on Universities

by our Special Correspondent

Universities in Britain are soon to have another intermediary in their increasingly uneasy relationship with the Government. From the beginning of next year the financial affairs of the universities will be open to audit by the Comptroller and Auditor General, the Government financial watchdog. Most of the universities are unenthusiastic about the idea, but need more details of how the scrutiny will operate before committing themselves.

MR ANTHONY CROSLAND has an uncanny talent for timing. His most unpopular announcements are always made a week or so before Parliament goes into recess—before Christmas it was the increase of fees for overseas students, last week the confirmation that university accounts are to be audited by the Comptroller and Auditor General. To the surprise of his department, this latest decision has so far raised far less steam than the fees issue. It comes, of course, as less of a surprise, as the Committee of Public Accounts of the House of Commons recommended it in a report published early this year

(*Nature*, 213, 438; 1967). In addition, it may be that universities, traditionally slow to react, are still embroiled in arguments with the University Grants Committee about equipment grants.

The Public Accounts Committee announced its recommendations in January this year. They were short and to the point; from August 1, 1967, the comptroller should be given access to the books and records of the UGC and the universities, and in the meantime steps should be taken both to work out suitable conventions as to how the scrutiny should be handled and to ensure that

the universities are fully informed about the nature and purposes of the scrutiny, and what it would in practice involve. Opposition—unexpectedly bitter and determined—centred on the fear that financial judgments would inevitably encroach on academic preserves. Lord Butler muttered darkly about dictatorship, the Committee of Vice-Chancellors and Principals about academic freedom. Nobody denied, though, that since the war the financial load of the universities on the Exchequer has gone up by leaps and bounds (see chart). This was the mainspring behind the committee's drive to make sure money was not being wasted.

Growth of support for universities in Britain from the public purse. Open areas represent recurrent grants, hatched areas capital grants. The estimate for 1966-7 is £211 million, £134.5 million in recurrent grants and £76.5 million in capital grants.

How will the new system work? Mr Crosland's statement left much unsaid. What it did make clear is that the UGC will continue to support the universities by way of block grants, and that the universities will be responsible for seeing how the money is spent. It will not be part of the comptroller's duty to question policy decisions or decisions reached on academic grounds. The department is going out of its way to make these points clear, and referring inquiries to the proceedings of the public accounts committee, in which almost every page contains an assurance that the comptroller will not intervene in matters falling outside his exact terms of reference. It is also known that the accounting officer for the universities will be the senior civil servant at the Department of Education and Science, Principal Secretary Sir Herbert Andrew. The department's attitude is to play down the importance of the change; really, it says, nothing at all has changed. It does not yet know exact details of how the scrutiny will be organized, and much of the time before the system comes into operation on January 1, 1968 will be taken up with working out the conventions, in discussion with the Committee of Vice-Chancellors and Principals and the UGC.

Until more information emerges, the interested parties are reserving their positions. As yet it is neither clear how the comptroller will go about his job, nor what he will do if he discovers anything discreditable in the university accounts. In the proceedings of the public accounts committee, Sir Bruce Fraser, the comptroller, gave some idea of how he would tackle the job. Asked how he would regard an experiment in teaching methods which had turned out to be expensive, he said that if on auditing the books he found an unexplained increase of this type,

he would ask why. If he were told that the increase had come about as a deliberate decision of academic policy, that is all he would wish to know. "I would say no more about it. It would be ridiculous for me to substitute my judgment for the academic judgment of the people who know about it."

A central figure in the new arrangements seems likely to be the accounting officer, Sir Herbert Andrew. As he is responsible for answering criticisms directed at the universities, he will probably act as the go-between in the relations between the universities and the comptroller. It is unlikely that anything so tasteless as a direct confrontation between the comptroller and the vice-chancellors would be tolerated, and Sir Herbert may well be thrust willy-nilly into the disputed ground between the two parties, as a sort of referee. As he will be expected to answer any criticisms which the comptroller has, he will have to be very well informed indeed about the activities of the universities. Talking to the committee of public accounts, Lord Murray of Newhaven, Chancellor of the University of Southampton, saw this as a danger: "The accounting officer would have to protect himself to meet his obligations . . . I think it would be difficult for him to stop at asking why as well as what expenditure is incurred".

The comptroller has for many years audited the books of one college, Cranfield College of Aeronautics. During the PAC hearings, it was suggested that the audit had had the effect of limiting the research and development at Cranfield. These suggestions, made by witnesses from the Association of University Teachers, were later withdrawn after representations by the college. It is fair to say that the college was embarrassed by the allegations, which did not correspond with its own experience. Although it does not feel that public statements by the college would be helpful at this stage, its experience of the comptroller has inevitably attracted interest.

Each year officials from the comptroller's department—the Exchequer and Audit Department—visit the college, look at the books, and ask questions. Their report then goes before the comptroller. If the comptroller is dissatisfied, or has further questions to ask, he approaches the DES, which will—if necessary—ask the college for further information. This, according to the Exchequer and Audit Department, is the normal, accepted form of audit; if the comptroller is not satisfied with the answers given, or if he can see any other reason for mentioning the matter, he may include a reference to it in his annual report to the Public Accounts Committee. Further discussion is then exclusively between the DES and the PAC. If this system is adopted with the universities, it will clearly increase the work load of the Exchequer and Audit Department—the present staff stands at about 450, of whom 400 are auditors. Although it is hard to see how an effective audit can be carried out without visiting the universities, some preliminary screening procedures may be adopted, in which the universities would send audited books to the DES. It is hard to believe, however, that the comptroller would be willing to protect universities' sensibilities by dispensing with visits altogether.

Where the UGC fits into the picture is even more obscure. Its traditional role as buffer between department and universities is beginning to look bedraggled, and these latest moves will do nothing to reassure either party. By a stroke of fortune, though, Mr Crosland has been supplied with an issue in which the intervention of a third party could perform a valuable public service. The argument between the universities and the UGC over equipment grants has been unusually bitter. The universities feel let down, while the UGC plaintively says that it only did its job. If the comptroller could sort out responsibility for the mess—and give some idea how it could have been avoided—the universities might begin to feel that he could perform a useful function.

# The East African Rift System

by

R. B. McCONNELL

Streatwick, Streat, Sussex

Dr McConnell joined the Geological Survey of Tanganyika in 1937 and worked there and in other parts of the African continent during the following eighteen years. He reviews here geological aspects of the East African rift structure which have a bearing on problems of the upper mantle and continental drift.

THE study of rift valleys has assumed a new importance in the past 10 years because of the discovery by Heezen<sup>1</sup> of comparable features on the world-wide system of mid-ocean ridges, and the International Upper Mantle Project<sup>2,3</sup> has shown considerable interest in the East African rift system. Previous reviews of this system have been published<sup>4-7</sup>, but it is now possible to give a clearer picture of the entire field because of the recent accumulation of detailed mapping since the post-war expansion of the Overseas Geological Surveys<sup>8</sup> and the establishment of the Research Institute of African Geology at the University of Leeds<sup>9</sup>, and it may be of value to outline the geological characteristics of the system in view of the latest work.

A rift valley may be defined as an elongated sunken area, with a characteristic width<sup>6</sup> of 30-60 km, which has

descended between parallel faults. The term was introduced by Gregory<sup>10</sup> to designate the grabens (down-faulted strips) of the great fracture (*Brüche*) system of eastern Africa, first described by Suess<sup>11</sup>. In the East African rift system, as now described, true rift valleys are numerous, but the rift faults, although forming a continuous system, are not always in pairs determining a graben, but may take the form of block faults or be replaced by flexures. The rift system was believed by Suess and Gregory to include the Red Sea and the Dead Sea-Jordan Valley complex, but only the portion within the African continent will be considered here.

The classical East African rift system, as shown in Fig. 1, is more than 4,000 km in length from Asmara, near the Red Sea, to the Zambezi River, and reaches a maximum

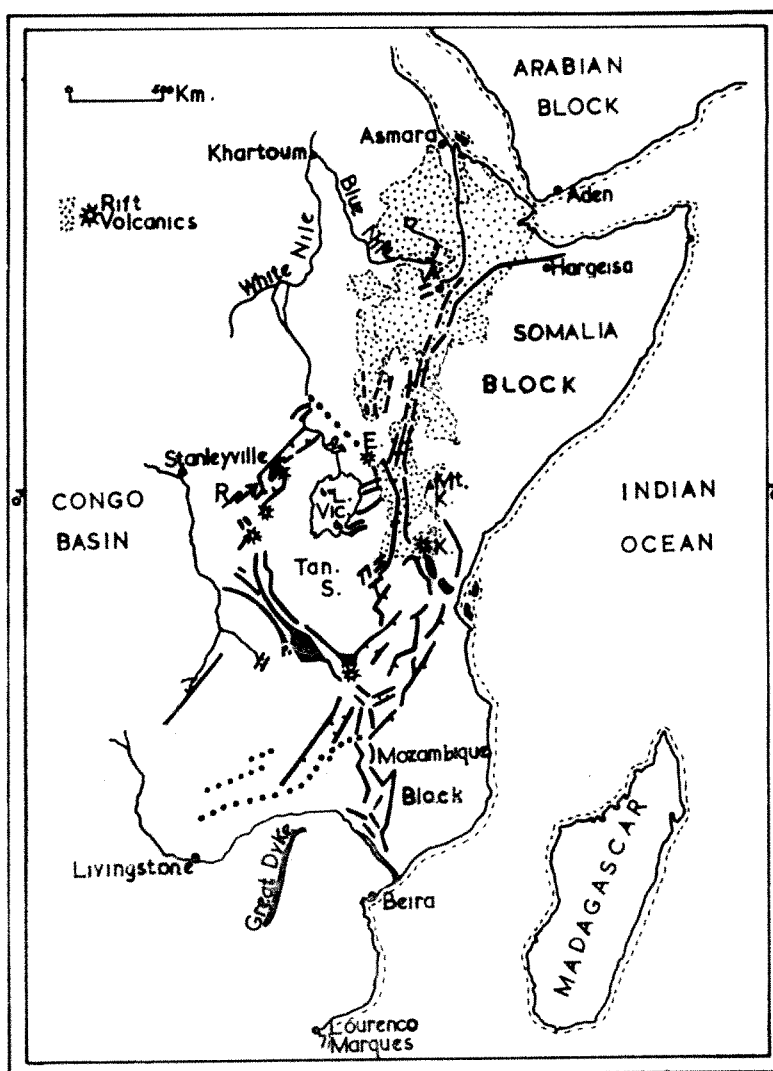

Fig. 1. Structural map of the East African rift system showing major rift scarps (schematized) and allied features. Solid black denotes raised blocks. Heavy dots denote dislocation zones. A, Addis Ababa; R, Ruwenzori Mountains; E, Mt. Elgon; Mt. K, Mt. Kenya; Tan. S., Tanganyika Shield; K Kilimanjaro.

width of 1,000 km in Tanzania. This immense system is much quoted in the literature of world tectonics, but its complexity is little understood because of the difficulty of synthesizing the many detailed investigations which are necessarily restricted to limited map sheets. Enough geological mapping is now available, however, to give a preliminary view of many important aspects of the rift system which concern: (1) the geological formations involved; (2) the pattern of faulting; and (3) the age of faulting.

Geological evidence<sup>5,12,13</sup> now appears to confirm that the pattern of the rift system originated in Pre-Cambrian times<sup>7,14,15</sup> as a line of deep faults centring on a N.N.E.-S.S.W. axis, diverted locally around pre-existing cratons, and that movements have occurred during major orogenic cycles down to the present. Dixey<sup>16</sup> has given evidence for the existence of actual rift valleys as early as the Jurassic, but during periods of stability the fault scarps and grabens were generally planed down by erosion<sup>17,18</sup> and even crossed by river systems.

It is a fact of outstanding geological importance that the formations principally affected are of Pre-Cambrian age; the pattern of rift faulting has been found to reflect the Pre-Cambrian structures of the basement and formations of later date are merely relatively thin cover rocks which conceal these structures. To attain an objective view of the history and geological structure of the rift system as a whole it is therefore necessary to give special consideration to those few areas, particularly in Malawi, Tanzania and Uganda, in which the remarkable Pre-Cambrian structures within the rifts are clearly visible, and not, as is the general rule, concealed by young volcanics and sediments, or by lake waters.

In view of the inherent difficulties of Pre-Cambrian geology, however, the study of the very significant association between rift faulting and Tertiary-Recent volcanism<sup>19-23</sup> which is so well exposed in the Kenyan and Ethiopian sectors is also most important for the unravelling of the history of the rift system. This volcanism<sup>24,25</sup> is characteristically alkaline and of great interest petrologically; the associated post-Miocene rift structures are also particularly clearly seen, but it must be remembered that these phenomena are typical only of the northern part of the system and that elsewhere Cainozoic volcanism is rare, being either completely absent or limited to intersections in the fault system.

A map, Fig. 1, showing the pattern of faulting compiled from the latest information<sup>26-31</sup> illustrates the difficulty, which results from the curvature of the component faults and grabens, of explaining the formation of the rift system by invoking either tension<sup>6,19</sup> or compression<sup>32-34</sup> alone. The strike of the components of the rift system varies between N.W.-S.E. and E.N.E.-W.S.W., but the map clearly indicates an overall N.N.E.-S.S.W. axis which is represented in the north by the strike of the Gregory and Ethiopian rift valleys. This axis is split into eastern and western branches by the resistance of a central craton termed the Tanganyika Shield<sup>7</sup>, thus giving rise to the great width of the system in its equatorial sector.

In the Ubende area of Tanzania, adjacent to Lake Tanganyika, a portion of the Pre-Cambrian floor of the western branch of the rift system is exceptionally well exposed. In 1943-44 I mapped the region and showed<sup>14</sup> that the N.W.-S.E. rift fault scarps in this area follow Pre-Cambrian movement zones identified by blastomylonites, phyllonites, migmatites and elongated anatectic granites whose origin was assigned to an Ubendian Diastrophism<sup>7</sup>. These metamorphic zones were later studied by Sutton and Watson<sup>35,36</sup> and the presence of Pre-Cambrian movement zones was confirmed. Similar associations and parallelism of Pre-Cambrian mylonites and migmatites with rift faulting have also been described from many different sectors of the rift system<sup>7</sup>, irrespective of strike.

At the southern termination of the rift system, in the Zambezi River sector, the fault pattern appears to split again around the Rhodesian Shield, and Vail<sup>37</sup> has described elongated troughs of Karroo sediments, to the east and west of this shield, which he believes to be the southern continuation of the rift system manifested by faulting in late Karroo and Cretaceous times. It has been pointed out elsewhere<sup>7</sup> that the line of the Great Dyke of Rhodesia continues exactly the strike of the Gregory rift system, and this line also bisects the Bushveld Igneous Complex. Cousins<sup>38</sup> has since shown that a chain of igneous complexes of Bushveld type follows this same line as far south as Trompsburg<sup>39</sup> (lat. 30° S.), a nearly straight line between the Zambezi and Orange rivers of some 1,500 km. The main axis of the rift system (Fig. 2) appears therefore, from present geological indications, to be a major N.N.E.-S.S.W. lineament (deep fault) of great age extending over a strike of some 5,500 km, diverted and split where penetrating pre-existing cratons representing the ancient core of Africa, and outlined by intrusive bodies which can be dated. This feature may be compared in strike with the great N.N.E.-S.S.W. fracture zones in the floor of the Indian Ocean, independent of the mid-ocean ridges, which have recently been described by Heezen and Tharp<sup>40,41</sup> and are schematically shown in Fig. 2.

The question of the age of the rift system can now be approached with more confidence in view of the recent synthesis of the geochronology of equatorial Africa by Cahen and Snelling<sup>42</sup> in which five geological cycles comprising syntectonic and post-tectonic episodes are described. An early cycle, sparsely represented by dates older than  $3,000 \times 10^6$  yr, is followed by the Shamvaian Cycle (compare Superior Cycle<sup>43,44</sup>) dated  $2,700-2,300 \times 10^6$  yr and recognized in East Africa. The term Ubendian is now firmly attached to a widely recorded cycle dated  $2,150-1,650 \times 10^6$  yr (compare the Svecofennid-Hudsonian

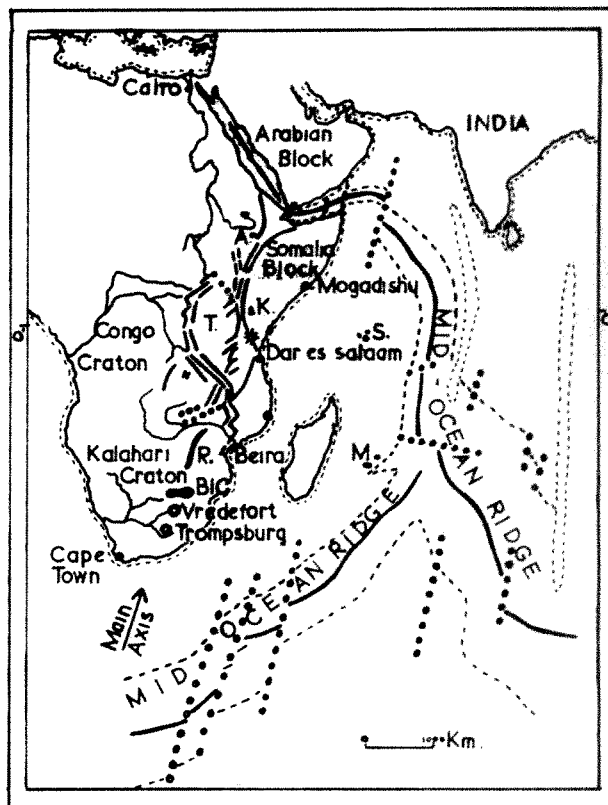

Fig. 2. Structural map illustrating main axis of rift system features of eastern Africa. Structure of Indian Ocean outlined after Heezen and Tharp. Black lines denote major fault scarps. cycle) in Tanzania (compare also ref. 54) and Uganda, where it coincides with the Buganda-Toro-Kibalian movements and granitization in the Western Rift (for example the Ruwenzori Mountains<sup>45,46</sup>). Table 1 shows that the chain of Bushveld type igneous complexes has given ages comparable with these early cycles. The latest investigation<sup>50</sup> of the Great Dyke of Rhodesia gives an age of  $2,530\text{--}2,800 \times 10^6$  yr, corresponding to the Shamvaian Cycle, and two independent and very thorough studies<sup>47,48</sup> of the Bushveld Complex have given Ubendian ages. Evidence from the Ruwenzori Mountains (ref. 45, p. 263) placed the age of the earliest rift faulting tentatively between  $2,500 \times 10^6$  and  $3,000 \times 10^6$  yr, and so, relating this result with the age of the Great Dyke, it is here suggested that an extensive dislocation of Africa, originating the East African rift system, took place in the Shamvaian Cycle. This original disruption was followed by the event now termed Ubendian, which imposed its isotopic age pattern on many of the migmatites and granites associated with the older event.

I have proposed<sup>7,45</sup> that the rift system arose in these early Pre-Cambrian times from a right-lateral wrench as a result of a tendency for the African continent to drift to the north-north-east while its eastern margin (Somalia, Mozambique) either remained fixed or drifted to the south-south-west. This hypothesis was based on the movement pattern observed around the Tanganyika Shield, which was postulated to be a pre-Ubendian craton around which the rift system had split. Later work has produced supporting evidence for early movements of this nature, but it must be emphasized that recent mapping has confirmed that no appreciable horizontal displacement has occurred along the rift faults since Ubendian times. If indeed the original movements were of lateral slip nature, then it must be supposed either that the strain pattern varied during the many later revivals, or that strike slip was impeded by the complication of the fault system along N.W.-S.E. and N.E.-S.W. lines, following the regmatic pattern<sup>55,56</sup>, and also by widespread granitization leading to a sort of "grouting" along fault zones. Renewed activity was, in any event, manifested by vertical<sup>12,21,57</sup> tectonics, perhaps accompanied in depth by metamorphic or magmatic activity as a result of the conversion of dynamic to thermal energy.

Later Pre-Cambrian cycles (including syntectonic and post-tectonic phases) are defined by Cahen and Snelling<sup>42</sup> as Kibaran (Karagwe-Ankolean) from  $1,290 \times 10^6$  to  $850 \times 10^6$  yr, and Katangan-Mozambiquian from  $1,100$  to  $450 \times 10^6$  yr. These episodes began with extensive deposition in basins which locally followed the pattern of the rift system<sup>9,42</sup>, although details are still under consideration, and were accompanied by extensive migmatization and granitization along the rift zones which are reflected in the

radiometric updating of previously consolidated areas. Evidence of sedimentation in basins along the rift system is clear in Karroo times<sup>4,18,37</sup> and this cycle was closed by extensive vertical movements in the Jurassic which appear to have been manifested by arching on an immense scale (compare cymatogeny<sup>58</sup>) followed by the formation of grabens, perhaps on the lines proposed by Cloos<sup>59</sup>. After a period of planation the same pattern of events appears to have been followed in time and in space during the Alpine cycle, which culminated in the formation of the present rift valleys and single scarps in post-Miocene times<sup>23</sup>.

At the present time the East African rift system is represented by rift valleys and fault scarps on a wide arch, elongated meridionally, forming the eastern high plateaus of Africa. This structure has been compared with the world-wide system of mid-ocean ridges with their central rift valleys<sup>60,61</sup>, but King<sup>22</sup> has pointed out fundamental geophysical and geological differences between these two systems, and it must be emphasized that the mid-ocean ridges are exclusively in oceanic crust and associated with geologically rapid spreading accompanied by the formation of new oceanic crust by the upwelling of basic magma<sup>62-65</sup>. The East African system, on the contrary, is confined to continental crust, and shows no spreading or formation of new crust. Any distension arising from graben faulting is slight because of the steepness and commonly antithetic nature of the fault planes: although many faults dip  $50^\circ\text{--}70^\circ$  towards the rift, vertical faulting is more widespread than has been generally assumed following Dixey<sup>6</sup>, but reverse faults are exceptional. There is a sharp contrast between the dyke-filled extension fractures of Iceland<sup>66</sup>, regarded as characteristic of a mid-ocean ridge, and the structure of a typical continental rift valley. The marked decoupling between structures in the oceanic crust and on the adjacent continent which is seen on the Pacific coast of North America<sup>68</sup> is also significant.

The physiographic and seismic characters of the East African rift system and the Red Sea-Gulf of Aden sectors of the world-wide mid-ocean ridges<sup>63,67</sup> are remarkably similar, however, and the close conjunction of the two systems in Ethiopia is a point of great importance and invites further detailed investigation.

It is intended to exclude theoretical considerations from this article so far as possible, but it may be suggested that the repeated rejuvenation along similar lines of movements which originated in early Pre-Cambrian times is of some significance and suggests that Africa has remained frozen to the higher layers of the upper mantle, and that the main N.N.E.-S.S.W. axis of the rift system reflects a deep-seated mantle lineament of great age. Belousov<sup>69,70</sup> has pointed out that the survival of regional structural characteristics over many geological periods reflects a permanent relationship between crust and upper mantle. In view of

Table 1. RADIOMETRIC DATES ALONG THE EAST AFRICAN RIFT SYSTEM

Formation	Reference	Rock and stratigraphic position	Locality	Sample	Method	Age ( $10^6$ yr)
Rusizi-Ubendian Belt	42	Kate Granite emplaced in Ubendian gneisses	Abercorn Dist., Zambia. $9^\circ$ S.; $31\text{--}5^\circ$ E.	Biotite	K : Ar	$1,725 \pm 70$

\* Value adjusted following Faure *et al.*, ref. 49.

the recent confirmation of spreading from the centre of the mid-ocean ridges<sup>64,65</sup>, the reality of continental drift becomes more and more widely accepted, but the historical persistence of structural features in the crust would support the opinion of Heezen<sup>71</sup> that this continental separation takes place by expansion of the earth<sup>6,44</sup>, combined with the formation of new oceanic crust, rather than by the drift of the crust over the mantle. The extent of Cainozoic volcanism in the northern sector of the system may be allied to the development of the Gulf of Aden-Red Sea oceanic-type rifts during the Alpine orogenic cycle<sup>67</sup>.

I thank P. E. Kent for critical comments, N. J. Snelling for advice on radiometric ages, and J. V. Hepworth and J. B. Kennerley for unpublished information on the rift system.

## Perception of Emotionally Toned Words

by

D. E. BROADBENT  
MARGARET GREGORY

MRC Applied Psychology Research Unit,  
Cambridge

Some theorists believe that the way in which words are perceived by the hearer depends on two different mechanisms. One mechanism may prevent the operation of the other to an extent depending on whether the words are pleasant, neutral or bad. The number of correct responses is found to be greatest for neutral words and least for bad words. Some features of the data support the theory of dual mechanisms.

If an obscene word is presented to a listener over a noisy telephone channel, he is less likely to report it correctly than he is to report other, socially acceptable, words at the same signal noise ratio. This fact has been the source of considerable activity among experimental psychologists over the past two decades, because of its obvious connexion with clinical difficulties, and because it seems at first sight to require a mechanism that is curiously inefficient. That is, it seems to suggest that a complete recognition mechanism for words exists in parallel with the mechanism

with which we can report consciously, and that the former can prevent the operation of the latter. The original experiments have therefore been subjected to a good deal of technical criticism. One line of attack has been that experimental subjects could well perceive the word and yet as a subsequent and perfectly conscious process be unwilling to say it or write it down in an academic setting; a second that it is well known that the probability of a word affects the efficiency of its perception, and that the probability of obscene words is not accurately known.

A great deal of experimentation directed at these and other points has therefore taken place, and has been adequately reviewed elsewhere<sup>1,2</sup>. In general, it would probably be fair to say that most investigators now believe that the effect is genuine, but many of the techniques used to report it seem to depend considerably on the personality of the particular subject and on the precise degree of the emotionality of the words. It is perhaps worth noticing that many experiments use, as a criterion of the emotionality of a word, the time taken by the subject to produce an association to it: and this may be unreliable. It appears to have been rare to use a technique such as that of Johnson, Thomson and Frincke<sup>3</sup>, namely, to get the emotional quality of the words assessed directly by samples of subjects. In any event, there remains the problem of the mechanism of the effect.

Recently, however, Broadbent<sup>4</sup> has had some success in applying a particular mathematical model to the related problem of the perception of words of different probability. The model used was that the perceptual mechanism contains a number of random variables each corresponding to one of the words in the language, and that perception corresponds to the selection of that variable which has the largest value on a particular occasion. Evidence from the senses is supposed to shift the average value of the correct variable, without eliminating its variability, and pre-existing biases of the mechanism are reflected by an increase, even in the absence of stimulation, of the mean values for corresponding variables. Such a process could be represented by a mechanism of the type suggested by Treisman<sup>5</sup> and Morton<sup>6</sup>, and it will be obvious that changes in the bias towards or against certain words do not involve any biologically unlikely mechanism which recognizes a word first and then decides not to admit sensory information. The bias applies whether or not sensory information is present.

Table 1

Stimulus of class I class II	Probability of		
	Correct answers	Wrong answer of class I	Wrong answer of class II
A	B	C	
D	E	F	

Unfortunately, the mathematical analysis of multiple alternative decisions of this kind is not sufficiently complete for application to experimental data, and Broadbent accordingly made use of an approximation developed by Luce<sup>7</sup>. The details need not be reproduced, as they are available elsewhere<sup>4</sup>, but it is worth noticing that it involves the assumption that the variances of the variables are equal. Given this approximation, one can test the model by gathering data in a table. When this was done (Table 1) the model appeared to be more plausible than traditional theories. That is, decision theory is as applicable to the perception of words as it has been shown to be for simpler signals<sup>8</sup>. In addition, however, and perhaps more importantly, in a table of this sort, certain relationships will hold if the difference between correct perceptions of two classes of word results purely from the bias factors in the mechanism. In that event, and if  $N_1$  is the number of words in the language in class 1 and  $N_2$  is the number of words in the language in class 2, then

$$\frac{A}{B} \times \frac{F}{D} = \frac{N_2}{N_1}$$

If, on the other hand, a difference in correct perceptions results entirely from a change in the amount of sensory information received, and there is no difference in bias

$$\frac{B}{C} = \frac{E}{F} = \frac{N_1}{N_2}$$

The former of these results did indeed hold for words of different probability in Broadbent's results, and it appears therefore that the classic effect of word probability arises entirely from pre-existing biases in the mechanism, and does not require any system of control by one recognition mechanism over another.

It seems obvious that the same technique should be applied to the perception of words of different degrees of emotionality, and we report here two experiments in which this has been done. The technique is relatively complex, and it is probably best therefore to state the method in a series of logical steps, even although some of them occurred in a different chronological order when the experiment was actually carried out.

**Step 1.** Sixty monosyllabic words were chosen from the word frequency count of Thorndike and Lorge<sup>9</sup>, all in the AA class: that is, having more than a hundred occurrences per million words. They were chosen to include twenty words of apparently pleasant emotional quality, twenty apparently unpleasant ones, and twenty neutral ones<sup>10</sup>. This assessment was confirmed by giving twenty-two Cambridge housewives a list of all the sixty stimulus words, and asking them to rate each word on a seven point scale for pleasantness/unpleasantness.

**Step 2.** The sixty words were then ordered randomly in a list, and recorded on one track of a tape, using a 'Vortexion' twin-channel recorder. On the other track of the tape, electronically generated wide-band noise was recorded, and the two channels were mixed to a single external speaker.

**Step 3.** Because of the dynamic range of speech, and the distinct possibility that the vocal level of the speaker might unconsciously vary with the emotional quality of the word, one cannot by physical control guarantee sufficiently identical stimuli. It is known, however, that word probability and emotionality effects are greatly reduced by a "forced-choice" technique, where the listener is told a small set of alternatives and asked to pick the one which he has heard. Consequently, the stimulus tape with its accompanying noise was played to a group of six subjects who were provided with the list of stimulus words. A forced-choice score for each word was thus available, obtained on the actual tape and sample of noise to be used in the principal experiment, so that it should accurately reflect the quality of the physical stimulus. By eliminating five words from each group of words, three groups each of fifteen were produced (see Table 2) which were equal in score on the forced-choice procedure, and only these stimulus words were scored in the remainder of the experiment.

**Step 4.** The tape was then presented to twenty-two housewives, aged between 20 and 50 years, who had no knowledge of the vocabulary and were instructed simply to write down whatever word they thought they had

Table 2. HIGH FREQUENCY WORDS

Class	Good		Neutral		Bad	
Stimulus words	bed	6.36	deep	3.73	bad	1.77
	clean	6.36	far	3.95	blood	2.86
	dream	5.36	fast	4.27	death	2.04
	eat	5.68	foot	4.04	fail	2.18
	good	6.36	long	4.14	fat	2.73
	health	6.00	mind	4.41	fear	1.36
	light	5.73	pay	4.94	hang	2.23
	nice	5.41	plain	3.59	hard	2.59
	peace	6.86	red	5.14	kill	1.23
	rose	6.68	round	4.45	late	2.82
	see	6.00	run	4.36	loss	1.69
	sleep	6.64	short	3.68	pain	1.45
	wash	5.54	square	4.00	poor	1.77
	wise	5.86	stop	3.77	sick	1.41
	wish	5.32	taste	5.27	war	1.18
	Mean rating	6.01		4.25		1.95
	Class boundaries	7.00-5.30		5.29-3.10		3.09-1.00

heard after each stimulus; they were encouraged to put down a word even if they felt very uncertain about its being correct. They were told that all the words were monosyllabic.

**Step 5.** From the answer sheets in this experiment, there were collected together those erroneous responses which were made to the forty-five selected words, and which lay in the same frequency class as the stimuli: that is, which were *AA* words. There were 125 such words, and these were administered to a fresh group of thirty-two housewives who were asked to rate them for pleasantness and unpleasantness by the same procedure as the original stimuli. This step therefore established how many errors were made in each class of emotional quality, to each class of stimulus, and ignoring words in the wrong frequency class. (An advantage of the mathematics used is that any responses outside the classes of interest can be ignored without affecting the argument.)

**Step 6.** In order to determine the relative numbers of words in each class in the language, a random sample of 103 words was obtained from the Thorndike-Lorge frequency count by taking all *AA* monosyllables on every fifth page of the book. These again were rated for pleasantness and unpleasantness by the same group of thirty-two housewives as was mentioned in step 5. This then allows the relative numbers of words of this frequency class in each emotional class to be decided using the same cutting points already set up for the stimuli and the error words.

**Step 7.** The entire procedure was then repeated for a different frequency class of words, namely, monosyllables occurring between ten and forty-nine times per million in the Thorndike-Lorge count. There were the following minor differences in the procedure: nine subjects were used for the forced-choice responses, and only four words were eliminated from each group of twenty to produce balance of the tape recordings. The stimulus words used are shown in Table 3. Thirty-two housewives were used as listeners in the chief experiment: they produced ninety-two error words of the same frequency class as the stimuli, and these were rated by another group of thirty-one housewives. Intermingled with the error words in this rating were 121 words from a random sample from the Thorndike-Lorge count including all monosyllables of the appropriate frequency on every seventh page of the book. (A lower proportionate sample is necessary to produce the same number of words for rating, because by Zipf's law there are more words in the language of low frequency than of high.) Because low frequency words are on the whole slightly less pleasant<sup>2</sup>, the boundaries between the three classes of emotional quality had to be rather different from those of the high frequency words, but, just as in the earlier experiment, the same boundaries

were used for the stimuli, for the erroneous responses, and for the sample from the Thorndike-Lorge count.

One fairly important difference from the earlier experiment was that the subjects listening to the tape recording were asked after each response to write whether they felt sure or unsure that it was correct. This attempt to get additional data was an afterthought, which will be seen to be of possible importance.

The chief features of the results are set out in Table 4. It will be seen, first, that there is undoubtedly an effect of the emotionality of the stimulus on the number of correct responses, even with the precautions that had been taken, and with words that are completely acceptable socially. For the high frequency words, neutral words are significantly better than good words,  $P < 0.01$  by the Wilcoxon test, and than bad words,  $P < 0.05$ . For the low frequency words, the neutral stimuli are only significantly better than the bad words,  $P < 0.001$ , and are no better than the good words. The bad words are, however, also significantly worse than the good words,  $P < 0.01$ .

Table 4

		Good	Neutral	Bad
High frequency words	Correct responses	19.39	30.91	23.63
	Errors averaged for all types of stimulus	10.45	27.78	2.53
	Sample from T-L count	23.30	71.84	4.86
	Ratio of errors	4.13	10.98	1
	Ratio of sample	4.80	14.80	1
Low frequency words	Correct responses	21.09	22.07	12.30
	Errors averaged for all types of stimulus	2.02	7.10	5.28
	Sample from T-L count	19.82	47.12	33.06
	Ratio of errors	0.38	1.34	1
	Ratio of sample	0.60	1.43	1
	Proportion of wrong responses labelled "sure"	0.36	0.34	0.53

Turning now to the number of errors of each emotional class, no systematic differences between different types of stimuli appeared, and in particular there was no tendency for errors to be of the same class of emotionality as the stimulus. The data for all kinds of stimulus have therefore been averaged, and at first sight the ratio of errors of different types appears to follow the numbers of correct responses and therefore to show a bias in favour of the use of neutral rather than good or bad words. This is not the case, however, as we can see from the comparison between the ratio of errors produced and of words sampled at random from the language. It is quite clear that the ratios are closely similar and differences between them are quite insignificant. Indeed, the differences actually obtained are in some cases in the wrong direction to explain the effect on correct responses. The only reason why people mostly use words of neutral emotional tone as their misperceptions is that there are more words of that type available for them to produce.

On the model used in this analysis therefore we have to suppose that emotional words do not behave like words of low probability: there is not a constant bias against them in the perceptual mechanism, but there appears actually to be a failure of the stimulus information to reach the perceptual mechanism. In terms of the familiar parameters of the theory of signal detection by human operators<sup>8,11</sup>, the effect is on  $d'$  and not on  $\beta$ , whereas the effect of probability is on  $\beta$  and not on  $d'$ . The difference is consistent with certain discrepancies between the probability and emotionality effects found by Newbigger<sup>12,13</sup>.

Frankly we were not expecting these results, and have been described at an informal level as showing "that Freud was right after all". Two chief possibilities suggest themselves as mechanisms by which the effect could

Table 3. LOW FREQUENCY WORDS

Class	Good	Neutral	Bad
Stimulus words	bath 6.42	barn 4.16	ache 1.90
	breeze 5.35	brass 4.71	bleed 1.97
	bride 6.39	brick 4.13	brute 1.29
	cash 6.03	chant 4.32	crash 1.32
	cruise 6.45	crow 3.29	cruel 1.03
	feast 6.19	flock 4.42	dirt 1.55
	hug 6.03	halt 3.74	dread 1.42
	lawn 5.90	hut 3.97	fog 1.77
	mirth 6.06	mode 4.00	fright 1.35
	neat 5.52	moist 3.26	grief 1.03
	peach 6.19	plough 4.77	guilt 1.23
	ripe 5.77	puff 3.96	mock 2.16
	soup 5.13	purse 4.77	scream 1.61
	spice 4.84	scarf 4.35	stale 2.06
	thrill 6.39	sixth 4.13	starve 1.19
	tune 5.64	starch 3.93	whip 1.74
Mean rating	5.89	4.11	1.54
Class boundaries	7.00-4.80	4.79-3.10	3.09-1.00

occur without requiring a complete duplication of the perceptual mechanism. First, it would be possible for those random variables in the model which correspond to emotional words to have in the absence of stimuli the same average value as those for neutral words. When rises in the value of such a variable occur, however caused, they produce some physiological change which reduces the level of sensory input. This would not prevent emotional words from occurring as wrong responses, but would make it less likely that they would occur as correct ones. This theory would have some difficulty, not perhaps completely fatal, with the fact that emotional words are no more common as errors to emotional stimuli than they are to neutral stimuli. If the information has been sufficiently extracted to have an effect on the sensory input, one would expect it to show in the nature of the error made.

The second possible theory is that which at present attracts us; and this is that our calculations have misrepresented the true state of affairs by supposing equal variances for each word. If the emotional words possessed a higher variance in the absence of stimulation, but the same mean value as neutral words, then the effect we have obtained would have been expected. That is, if emotional words were sometimes receiving a positive bias and sometimes a negative one, because of passing states of mood, and did this to a greater extent than neutral words but received the same change in their mean value from sensory information, then we would expect the results that have actually been obtained. Unfortunately, there is no way of checking this conjecture, except through the judgments of "sure" and "unsure" which were obtained in the experiment on low frequency words. Not only is there no established way of analysing experimental data if the underlying decision process is of unequal variance, but there is even less possibility of assigning a meaning to ratings of confidence in a multi-alternative situation. The following argument, however, seems intuitively clear.

Let us ignore the ratings of confidence on correct responses, and consider only those on errors. Whatever the mechanism for assigning confidence to an erroneous response, it would seem plausible that a higher proportion of responses would receive a high rating of confidence if the variable underlying them has a larger variance. The upper tail of the distribution of such a variable will stand out above the upper tails of variables with a smaller variance. In fact the proportions of error responses labelled "sure" rather than "unsure" are given in the last line of Table 4, and it will be seen that bad words tend to be produced as errors very confidently, as compared with neutral words. There is therefore some evidence, albeit lacking in rigour, that the resting bias on bad words varies more seriously than that on neutral words, and this might conceivably explain the difficulty of perceiving them. As things stand, however, it is clear only that the emotionality of words has an effect on their perception which is different from that of probability, and that it is not to be explained by a steady bias against such words in the perceptual mechanism before sensory evidence is received.

## Significance of the Binding of Iron by Transferrin

by

J. FLETCHER\*

E. R. HUEHNS

MRC Group in Haemolytic Anaemias,  
University College Hospital Medical School,  
London, W.C.1

Iron is carried in blood plasma by the protein transferrin, which is able to carry two atoms of iron. The availability of bound iron to immature red blood cells seems to vary according to the way in which the iron is distributed on the molecule of transferrin.

THE fact that the plasma iron is carried on a single protein, transferrin, does not necessarily mean that it forms a uniform pool<sup>1</sup>. Each molecule of the protein can carry two atoms of iron, and because complexing with iron produces changes in the conformation or charge of the protein<sup>2,3</sup> there may be differences between molecules carrying one or two atoms of iron. There may also be differences in the behaviour of iron atoms attached to one of the two binding sites rather than the other.

The first set of experiments was devised to test whether or not iron bound to transferrin in the plasma is uniformly available for uptake by immature red cells. Iron free plasma was labelled with a mixture of iron-59 and carrier iron approximately to half saturate the total iron binding capacity (level A). The iron free plasma was prepared by dialysis against acetate buffer pH 6.0, containing 0.01

molar sodium EDTA followed by dialysis to pH 7.4 in a buffer containing Krebs-Ringer bicarbonate. Complete removal of EDTA was ensured by dialysis against several changes of the latter buffer. The radioactivity present in the plasma was then proportional to its total content of iron. This plasma was incubated with reticulocytes until approximately half of the iron had been removed (level B). A control plasma was prepared by adding the same mixture of iron-59 and carrier iron to a further sample of iron free plasma until the percentage saturation of the two samples was equal at level B. The uptake of iron into fresh reticulocytes from both samples was then measured during incubation at 37° C (Fig. 1). It will be noted that in both plasmas the amounts of radioactivity, total iron and transferrin, as well as reticulocytes, were equal. If some iron bound to transferrin, however, is preferentially available to the reticulocyte most of this will have been removed from the sample of plasma which was pre-

\* Watson Smith Research Fellow of the Royal College of Physicians, London.

incubated. The reduced uptake of iron by fresh reticulocytes from the preincubated plasma is therefore consistent with the idea that the iron in the plasma is not a uniform pool but that some is more readily available than the rest. As a control experiment, a mixture of iron-59 and carrier iron was added to both samples to restore the total iron from level B to level A, the level in the test sample before any treatment with reticulocytes. As expected, the difference was markedly reduced, falling from 61 per cent to 12 per cent. Similar results were obtained when plasma from a patient with severe iron deficiency was used instead of dialysed plasma. This result excluded the possibility that the observed differences in uptake were due to denaturation of the transferrin during the dialysis procedure. It is therefore concluded that all iron bound to transferrin is not equally available to immature red cells.

The cause of this could be either preferential uptake of iron from saturated transferrin,  $\text{Tf}(\text{Fe})_2$ , rather than from half saturated molecules,  $\text{Tf}(\text{Fe})_1$ , or the preferential uptake from some binding sites. When unlabelled iron is added to both the preincubated and the control samples of plasma to saturate the iron binding capacity, the difference in uptake persists. In these conditions only  $\text{Tf}(\text{Fe})_2$  molecules are present, and so the difference must be caused by different rates of uptake from some of the binding sites.

The factors that determine which iron is removed first by reticulocytes were further investigated by a different type of experiment. In this, the rates of uptake of iron-59 by reticulocytes added at different percentage saturations of transferrin were directly compared. In order to get a valid comparison, the total iron, transferrin and radioactivity in each sample must be identical and this can be achieved by a method developed from that used by Schade to test the integrity of purified transferrin<sup>4</sup>. A tracer amount of iron-59 is added to equal amounts of two plasmas, A and B, and allowed to combine with the transferrin. To plasma A an equal amount of unlabelled plasma B is added and to plasma B an equal amount of

Fig. 2. Scheme for the comparison of  $^{59}\text{Fe}$  uptake by reticulocytes from labelled plasmas. The method ensured that samples are identical in all respects except that  $^{59}\text{Fe}$  is attached to the normal plasma in one case and the abnormal plasma in the other.

unlabelled plasma A is added (Fig. 2). The two samples are now identical except that in one case the radioactive label is on plasma A while in the second it is on plasma B. The uptake of radioactivity by reticulocytes from each sample is then measured. In the first experiment of this type a fresh plasma at 25 per cent saturation was divided into two parts and the saturation of one increased to 50 per cent by adding cold iron. The uptake of iron-59 from each sample by reticulocytes was then measured as described here. Iron-59 added at 50 per cent saturation was taken up by the reticulocytes more rapidly than that added at 25 per cent saturation (Fig. 3). In contrast to this, total iron uptake from both samples was identical. The difference in uptake of iron-59 disappeared when both mixtures were saturated with cold iron before uptake was measured. In interpreting these results it has to be remembered that the added iron-59 reflects the binding sites on transferrin originally not occupied by iron. Iron added to plasma *in vitro* combines with the binding sites at random<sup>5</sup> and therefore according to their availability. At low percentage saturation there will be a large pool of iron free transferrin, some  $\text{Tf}(\text{Fe})_1$ , and very little  $\text{Tf}(\text{Fe})_2$ , so that a tracer amount of iron-59 will combine mainly with iron free transferrin to produce labelled  $\text{Tf}(\text{Fe})_1$ . At greater saturations the pool of iron free transferrin will be smaller, whereas the amount of  $\text{Tf}(\text{Fe})_1$  and of  $\text{Tf}(\text{Fe})_2$  will increase, and added tracer iron-59 will combine more frequently with  $\text{Tf}(\text{Fe})_1$  to produce labelled  $\text{Tf}(\text{Fe})_2$ , that is  $\text{Tf}(\text{Fe})_2$  ( $^{59}\text{Fe}$ ). The results of this experiment therefore show that there is a difference in behaviour between half saturated,  $\text{Tf}(\text{Fe})_1$ , and saturated,  $\text{Tf}(\text{Fe})_2$ , forms of transferrin, for at 50 per cent saturation many more saturated molecules are labelled than at 25 per cent. Final saturation with cold iron converts all molecular species to the saturated form,  $\text{Tf}(\text{Fe})_2$ , and so the difference in uptake of the label disappears. At any given saturation the relatively small quantity of iron added as iron-59 will produce very few doubly labelled molecules  $\text{Tf}(\text{Fe})_2$  at either level of saturation. The difference observed is therefore caused by a specific effect of carrying two iron atoms rather than one iron atom and not merely that reticulocytes remove both iron atoms from one molecule of transferrin. Indeed, if the difference were caused by doubly labelled molecules it would not disappear when the mixture is finally saturated with cold iron.

The following experiments show that the effect of percentage saturation is not the only factor, but that there is

Fig. 3. Comparison of uptake by reticulocytes of  $^{59}\text{Fe}$  from plasma at different percentage saturations using the labelling method given in Fig. 2.  $\bullet$ , Tracer  $^{59}\text{Fe}$  added at 50 per cent saturation;  $\circ$ , tracer  $^{59}\text{Fe}$  added at 25 per cent saturation.

also a functional difference between some of the binding sites, the iron attached to some being preferred by reticulocytes. Plasma was divided into two parts and the saturation of one part was reduced by incubation with reticulocytes before performing the experiments described earlier (Fig. 2). Again, the uptake of the label was faster from the plasma with the greater percentage saturation (Fig. 4a). When both mixtures were saturated with cold iron, however, the uptake became faster from the mixture in which the label had been added to plasma at a smaller percentage saturation, that is the plasma preincubated with reticulocytes (Fig. 4b). This suggests that some binding sites preferentially deliver their iron to the reticulocytes.

Having defined these two effects it is possible to confirm that they occur *in vivo* by examining plasma from patients with inactive and overactive erythropoiesis. The same technique (Fig. 2) is used with normal plasma and plasma from suitable patients. The results are shown in Table 1. When the labelled iron is attached to plasma from patients with aplastic anaemia it is taken up by reticulocytes more slowly than would be expected from the percentage saturation and this behaviour is accentuated by saturation of the final mixtures with cold iron. By contrast, uptake from the plasma of patients with overactive erythropoiesis (haemolytic anaemias) is faster than from normal plasma with comparable percentage saturation of iron. This is in keeping with the idea that overactive erythropoiesis clears iron from some sites in preference to others. The difference, however, between the control plasma and the test plasma on saturation was only maintained in some instances. The interpretation of this result is at present not clear.

The evidence presented supports the view that the plasma iron is not a single pool equally available for uptake by immature red cells. The availability varies according

to the way in which the iron is distributed on the carrier protein, transferrin. There appear to be two distinct effects and these may be important at different stages in the process of iron uptake by reticulocytes. The first step in this process is the combination of transferrin with a receptor on the cell surface. The work of Jandl and Katz<sup>6</sup> suggests that a difference between saturated and half saturated transferrin would be important at this stage probably because the saturated molecular species competes more successfully for the receptor than the half saturated species. The difference between binding sites will presumably affect the next stage when iron is taken up into immature red cells, the iron on some sites being preferred. It is not suggested that the other sites are unable to deliver iron to these cells, for reticulocytes can clear transferrin almost completely of iron.

## Gravitational and Cosmological Red-shift for Quasars

by

N. DALLAPORTA\*

Institute of Mathematical Sciences,  
Madras

Barbieri has shown that it is possible to differentiate between the gravitational and cosmological components of the red-shift of quasars by observational means. On the other hand, the interpretation of the results depends to a considerable extent on whether the source is considered to be static or expanding.

Most of the work on the nature of quasi-stellar sources, following the principal line of the basic paper by Greenstein and Schmidt<sup>1</sup>, has been based on a somewhat *a priori* assumption about the physical cause of the red-shift  $z$ . Recently, however, Barbieri<sup>2</sup> has shown that the relative importance of both its possible cosmological and gravita-

tional parts  $z_c$  and  $z_g$  can be obtained from purely experimental data, if the quasar is assumed to be constructed according to a model of the Greenstein-Schmidt type. Barbieri's procedure is based on six equations. These include the three relations 1, 2 and  $3b + 4a$  of Greenstein and Schmidt, expressing the gravitational red-shift  $z_g$ , the width  $w_g$  of emission lines due to the gravitational

\* On leave of absence from Istituto di Fisica, Università di Padova.

effect and the relation between observed brightness  $F$  of  $H_\beta$  and emission from the volume of ionized hydrogen where the lines are produced.

$$z_g = \frac{\Delta\lambda_g}{\lambda_0} = \frac{GM}{c^2 R} = 1.47 \times 10^5 \frac{M/M_\odot}{R} \quad (1)$$

$$w_g = \frac{\Delta R}{R} \Delta\lambda_g = \frac{\Delta R}{R} \lambda_0 z_g \quad (2)$$

$$4\pi r^2 F = 4\pi R^2 \Delta R E \quad (3)$$

where  $M$  and  $R$  are the mass and radius of the quasar,  $G$  the gravitational constant,  $c$  the velocity of light,  $\Delta R$  the depth of the atmosphere surrounding the dense core in which the emission lines are formed,  $r$  the distance of the quasar and  $E$  the volume emissivity in  $H_\beta$ .

To these are added three further relations, giving the total red-shift, the connexion (for a euclidian metric) of the cosmological red-shift with distance, and the geometrical relation between distance and the diameter of the quasar

$$z = z_g + z_c \quad (4)$$

$$r = \frac{cz_c}{H} \quad (5)$$

$$\frac{2R}{r} = \frac{\theta}{K} \quad (6)$$

$H$  is the Hubble constant,  $\theta$  the angular diameter in seconds of arc and  $K = 2.06 \times 10^5$ .

These six equations make it possible to determine the six unknown characteristics of the quasar,  $M$ ,  $R$ ,  $\Delta R$ ,  $r$ ,  $z_g$ ,  $z_c$ , for all the other quantities necessary can be obtained experimentally, at least in principle; and, using the results so far available for 3C 273, Barbieri obtains as the chief feature of this quasar a high ratio for  $z_g/z_c$ , of the order of 10–100, depending on the magnitude of the line width  $w$ , and a distance  $r$  reduced by a factor between 4 and 10 in respect of the purely cosmological one.

This procedure, of course, hinges on the assumptions fixing some of the quantities necessary to solve equations (1)–(6), and mainly on the line width  $w$ , which is taken to be the sum of the gravitational width  $w_g$  plus the width  $w_s$  due to the scattering of the line in the emitting atmosphere. This latter quantity can be evaluated theoretically<sup>3</sup> and has in fact been estimated for several lines of different quasars, including 3C 273, by Burbidge *et al.*<sup>4</sup>;  $w_g$  is then obtained by subtracting  $w_s$  from the total measured width  $w$ .

The model for a quasar underlying these considerations thus turns out to be static, in the sense that possible changes occurring in its structure are considered to be sufficiently slow not to produce any detectable effect. Most of the phenomenology which is actually being observed on several quasars, however, seems rather to suggest a dynamical situation, usually described as a state of expansion of the inner core, either continuous or in separate outbursts. Barbieri is induced by these facts to go somewhat beyond his own assumption by completing it on the following lines: the higher red-shifts of quasars in respect to radio galaxies may be due to their excess gravitational red-shift; and it might be expected that, because of expansion, these highly concentrated structures could gradually transform to normal radiogalaxies, readjusting their red-shift in the process to its natural cosmological proportionality with distance.

It thus appears that a logical extension of Barbieri's procedure might consist in dropping his static assumption, and completing his set of equations by a further group expressing the dynamical consequences of the expansion of the quasar. We have then to consider an expansion width  $w_e$  of the emission lines to be added to the other

widths, while the expansion red-shift  $z_e$  can be completely neglected in respect to the cosmological red-shift, because the maximum expansion velocity, when all the line width is attributed to emission, could at most be of the order of 1,000 km/sec.

The aim of this note is to present a very simple consequence which follows immediately from the introduction of this new term.

Let us in fact add the following equations to equations (1)–(6)

$$w_g = w - \Delta s - w_e \quad (7)$$

$$w_e = \frac{2v}{c} \lambda_0 \quad (8)$$

where  $\Delta s$  is an appropriate correction for the broadening due to scattering, and  $v$  is the expansion velocity of the atmosphere emitting the lines.

Although  $w_e$  cannot be evaluated because we are unable actually to measure  $v$ , we can, however, assuming that the system is expanding, already put as a lower limit for  $v$ , the value  $v_e$  of the escape velocity

$$v_e = \sqrt{2GM/R}$$

By introducing this expression into equation (8), equations (1)–(8) can be solved in respect to the six unknowns already mentioned and  $w_e$  and  $w_g$ , yielding the minimum values of  $w_e$  and  $z_c$ , and therefore the maximum values of  $w_g$  and  $z_g$ , compatible with expansion. We thus get for the ratio  $z_g/z_c = 1/y^2$

$$\frac{1}{A} = (y^2 - 1) \left[ 1 - \frac{B}{y} \right] \quad (9)$$

where

$$A = \frac{cE\theta^3(w - \Delta s)}{8K^3 H \lambda_0 F} \quad B = \frac{2\sqrt{2z} \lambda_0}{w - \Delta s}$$

It is immediately apparent from the expression for  $B$  that in all known cases it will be larger than unity. On the other hand, the right-hand side is negative when  $y < B$ , and therefore no solutions exist. For  $y > B$ , the right-hand side is positive and increases steadily from 0 to  $\infty$  as  $y$  increases from  $B$  to  $\infty$ . There is therefore a solution  $y$  for any value of  $A$ ;  $y = B$  for  $A = \infty$ , and increases steadily as  $A$  decreases.  $y = B$  is then the minimum value which can be obtained for any  $A$  and corresponds to the highest percentage of gravitational red-shift. Let us apply these considerations to the case of 3C 273  $B$ , and take  $z = 0.158$ ;  $\lambda_0 = 4861 \text{ \AA}$  ( $H_\beta$ ),  $w = 50 \text{ \AA}$ . Even neglecting the scattering correction  $\Delta s$  in order to get the smallest possible value, we obtain

$$B = 1.1 \times 10^2$$

From this we get the upper limit for the gravitational red-shift

$$\frac{z_g}{z} = 0.83 \times 10^{-4}$$

quite irrespective of any other determination of the remaining parameters of the source.

The argument can be easily extended even to distant quasars, for which the correlation between distance and red-shift may be non-linear and usually expressed as

$$r = \frac{c}{H} f(z_c) \quad (5a)$$

where  $f(z_c)$  may be any function always increasing with  $z_c$ , depending on the special cosmological model. Then equation (9) must be replaced by

$$\frac{1}{A} = \frac{y^2}{z} f \left[ z \left( 1 - \frac{1}{y^2} \right) \right] \left( 1 - \frac{B}{y} \right) \quad (9a)$$

and, as the right-hand side is again positive and increases steadily with increasing  $y$ , when  $y > B$  and  $z$  is kept constant for any quasar, the proof follows in exactly the same way, and  $y = B$  is again the solution corresponding to the highest possible gravitational red-shift. This conclusion still holds when the exact expression for the gravitational red-shift is used instead of equation (1). Barbieri's type of approach to the analysis of quasars, although apparently phenomenological and a straightforward way for gathering objective information, is still strongly dependent on the fundamental assumptions concerning the nature of the source. In fact, should we assume that quasars are in a static phase, a rather important percentage of the red-shift should be gravitational. If, on the other hand, quasars are expanding, then we are compelled to set an upper limit to the gravitational red-

shift which is practically negligible. Should quasars be structures alternatively quiescent and active as the phenomenological distinction between quasi-stellar objects and quasi-stellar sources might indicate, we should expect to find substantial differences in the emission lines between these two phases; QSS lines should be broader than QSO lines, because the expansion width is added to the basic gravitational contribution; this does not appear to be the case according to the present data.

## In vitro Synthesis of Bacteriophage Lysozyme

by

W. SALSER  
R. F. GESTELAND  
A. BOLLE

Institut de Biologie Moléculaire,  
Geneva

Active lysozyme of bacteriophage  $T_4$  has been synthesized in a cell free system programmed by RNA from cells infected with the phage. The appearance of this lysozyme activity has the characteristics of *de novo* synthesis.

THE advantages of achieving the *in vitro* synthesis of active enzymes in a well characterized system are many. Not only would it allow a more precise definition of the components and conditions necessary for protein synthesis, but it should also provide a useful method for the study of factors controlling the rate of protein synthesis, at the level of translation or transcription. Until now, however, there have been few studies of *in vitro* synthesis of specific proteins, and only in the case of haemoglobin and of proteins programmed by genomes of RNA viruses<sup>1-4</sup> have peptide analyses shown good correspondence between the *in vitro* and natural products. Unfortunately, none of these products has enzyme activity, which makes it difficult to assess the fidelity of the *in vitro* translation.

Of particular importance will be the development of systems where DNA from organisms with well defined operator-repressor control is the source of genetic information. Thus the findings by DeVries and Zubay<sup>5a</sup>, Schweiger, Traub and Zillig (personal communication), and Imai *et al.*<sup>5b</sup>, on the DNA dependent synthesis of a fragment of  $\beta$ -galactosidase, of  $T_4$  deoxycytidylate deaminase and tryptophane synthetase, respectively, are of great interest. In this direction we have been looking for synthesis of  $T_4$  specific proteins using RNA extracted from phage infected cells. Initially we feared that the extracted RNA might be partially degraded so that it could not direct the synthesis of complete proteins, but this is not the case. Our first series of experiments showed the efficient synthesis of at least a fragment of the head protein of  $T_4$  in extracts from uninfected cells. This suggested that modifications of the translation machinery caused by  $T_4$  infection<sup>6-9</sup> are not essential for reading the head protein messenger.

Soon afterwards we found that active  $T_4$  lysozyme is made in the same system. This enzyme was chosen in particular because the assay is very sensitive and because it is a relatively small protein (molecular weight 18,000) with a single well characterized polypeptide chain<sup>10</sup>. Moreover, extracts of uninfected *E. coli* lack lysozyme, so that the use of  $T_4$  mRNA in these extracts precludes

possible artefacts such as chain completion or activation of pre-existing enzyme.

We present here the results of our experiments with lysozyme, and those concerning the head protein will be reported elsewhere.

The RNA used to programme the *in vitro* lysozyme synthesis was prepared as follows. *E. coli* RNase  $I_{10}$  (ref. 11) was grown in *M-9* medium and infected with  $T_4$  D as described in method III of Bolle, Epstein, Salser and Geiduschek (submitted to *J. Mol. Biol.*). Cultures containing about  $3 \times 10^{12}$  cells were poured on ice and collected in a Sharples continuous flow centrifuge. To extract the RNA, the cells were resuspended in 40 ml. of 0.01 molar potassium chloride, 0.005 molar magnesium chloride, and 0.01 molar *tris* buffer, pH 7.3. Egg-white lysozyme was then added to a final concentration of 300  $\mu$ g/ml., and the suspension was frozen in liquid air. The cells were thawed and sodium dodecyl sulphate was added to a final concentration of 1 per cent. The viscous solution was briefly warmed in a bath at 64° C until a decrease in opacity of the suspension indicated cell lysis. Sodium acetate buffer, pH 5.2, was then added to a final concentration of 0.1 molar, followed by an equal volume of phenol saturated with water. The phenol extraction lasted 4 min and was carried out in a New Brunswick rotary shaking water bath at top speed and 64° C. The temperature of the extraction mixture reached about 61° C during this time. The aqueous phase was extracted with phenol a second time in the same way and the RNA was precipitated from 2 molar sodium chloride with 1.5 volumes of ethanol. The precipitated RNA was washed three times with 70 per cent ethanol plus 0.01 molar *tris*, 0.01 molar sodium chloride, dissolved in water and clarified by centrifugation at 27,000*g* for 20 min. After dialysis against deionized water for 4 h the concentration of RNA was adjusted to 8 mg/ml., and the solution was frozen in small samples and stored at -20° C. More vigorous techniques, such as five phenol extractions lasting 8 min each at 68° C, have also given RNA that is active for *in vitro* synthesis of lysozyme, but the result is

less dependable and considerable degradation of  $^{23}\text{S}$  RNA has been observed in such cases.

$S\text{-}30$  extracts from *E. coli* strain RNase  $I_{10}^-$  were prepared by the method of Nirenberg and Matthaei<sup>12</sup> as used by Capecchi<sup>3</sup>. The cell free extracts were dialysed for 6 h against 10 mmolar magnesium acetate, 10 mmolar *tris* buffer, pH 7.5, 30 mmolar potassium chloride, and 6 mmolar mercaptoethanol, frozen in small samples and stored at  $-20^\circ\text{C}$ . Before each experiment the  $S\text{-}30$  extract was pre-incubated for 30 min at  $36^\circ\text{C}$  to reduce endogenous protein synthesis. The pre-incubation mixture contained in each ml. 0.5 ml. of  $S\text{-}30$  extract; 50  $\mu\text{moles}$  of *tris* buffer, pH 7.8; 60  $\mu\text{moles}$  of ammonium chloride; 1  $\mu\text{mole}$  of dithiothreitol (Cleland's reagent); 0.1  $\mu\text{mole}$  of each of nineteen amino-acids (minus leucine); 0.02–0.04  $\mu\text{mole}$  of leucine (as indicated); and 5  $\mu\text{mole}$  of magnesium acetate in addition to the 5  $\mu\text{mole}$  from the  $S\text{-}30$  extract. It was found that the addition of an energy generating system during the pre-incubation does not give a further reduction in the endogenous activity.

The incubation mixture for *in vitro* protein synthesis contained in each ml. (including the contribution of the pre-incubation mixture): 0.25 ml. of pre-incubated  $S\text{-}30$  extract (final protein concentration of about 3 mg/ml. and 70S ribosome concentration of about 1 mg/ml.); 63  $\mu\text{moles}$  of *tris* buffer, pH 7.8; 50  $\mu\text{moles}$  of ammonium chloride; 8  $\mu\text{moles}$  of magnesium acetate (unless stated otherwise); 0.14  $\mu\text{moles}$  each of nineteen amino-acids (minus leucine), tritiated leucine (4 mc./ $\mu\text{mole}$ ) to give the specific activities indicated; 3  $\mu\text{mole}$  of ATP; 0.2  $\mu\text{moles}$  of GTP, 5  $\mu\text{moles}$  of phosphoenol pyruvate; 20  $\mu\text{g}$  of pyruvate kinase; 5  $\mu\text{moles}$  of polyethylene glycol of average molecular weight 6,000, and RNA fractions as indicated. The polyethylene glycol was added because it caused a 1.2–3-fold stimulation of the rate of incorporation of amino-acids (unpublished work of Gesteland). After incubation of the mixture at  $36^\circ\text{C}$  for the times noted, 0.1 ml. samples were removed and frozen for later assays of lysozyme. Incorporation of tritiated leucine into material insoluble in hot trichloroacetic acid was determined on another sample.

Fig. 1 shows the stimulation of incorporation of tritiated leucine into polypeptide, *in vitro*, by various concentrations of the RNA preparations. Bacteriophage  $R_{17}$

Fig. 1. RNA dependence of incorporation of amino-acids. Each point represents the hot trichloroacetic acid insoluble material in 0.1 ml. of reaction mixture. Incubation was for 20 min and the specific activity of the leucine was about 160 c.p.m./ $\mu\text{mole}$ , assuming no dilution of the 0.005  $\mu\text{moles/ml.}$  of added leucine. (A)  $R_{17}$  RNA; (B)  $T_4$  20 min RNA; (C)  $T_4$  5 min RNA; (D) RNA from uninfected *E. coli*.

RNA (refs. 4 and 13), which is used as a standard messenger for comparison, normally produces a thirty- to eighty-fold stimulation over the background with no added RNA. The RNA extracted from uninfected *E. coli*, or from cells infected for 5 or 20 min with  $T_4$  ( $T_4$  5 min RNA or  $T_4$  20 min RNA), is three to seven times less active on a weight basis than  $R_{17}$  RNA. Because, however, only 3 per cent of the *E. coli* RNA (Salser, Janin and Levinthal, *J. Mol. Biol.*, in the press) and 5 per cent of the  $T_4$  RNA (ref. 14) is messenger, this mRNA fraction is, if anything, more active than  $R_{17}$  RNA. The *E. coli* and  $T_4$  RNAs tend to saturate amino-acid incorporation at lower levels than does  $R_{17}$  RNA.

Typical results of lysozyme assays are shown in Fig. 2, where turbidity of the lysozyme substrate is plotted as a function of time. If a sample from an *in vitro* protein synthesis mixture, incubated with no added RNA, is mixed with the substrate, there is a slow background decrease in the turbidity (curve A). Curve B shows the result obtained when the *in vitro* system is supplemented with RNA extracted from cells 20 min after infection with  $T_4$ . The rapid decrease in turbidity indicates the presence of active lysozyme. Table 1 gives the data for incorporation of tritiated leucine and for lysozyme activity calculated from the maximum slope of curves such as these.

Fig. 2. Lysozyme assay. The substrate consists of *E. coli* B cells treated with chloroform and washed by the method of Sekiguchi and Cohen<sup>15</sup> but containing in addition to 0.05 molar *tris* buffer, pH 7.5, 1 mmolar magnesium acetate and 0.6 mmolar mercaptoethanol. The substrate is pre-incubated at  $25^\circ\text{C}$  for 10 min, then 0.1 ml. of an *in vitro* incubation mixture is added to each cuvette containing 1.0 ml. of the substrate. Lysis of the cells is followed at 450 mμ and  $25^\circ\text{C}$  in a Gilford recording spectrophotometer. The initial optical density is 0.4. The *in vitro* system was supplemented with: (A) no added RNA; (B)  $T_4$  20 min RNA (400  $\mu\text{g/ml.}$ ); (C)  $T_4$  5 min RNA (400  $\mu\text{g/ml.}$ ); (D) RNA from uninfected cells (400  $\mu\text{g/ml.}$ ).

In spite of the stimulation of incorporation of tritiated leucine by RNA from uninfected cells or from cells infected for only 5 min with  $T_4$ , neither RNA stimulates the production of lysozyme activity, as is shown in curves C and D of Fig. 2, and in Table 1. The lack of activity of the 5 min RNA is expected because *in vivo* synthesis of phage lysozyme does not begin until after this time<sup>16</sup>.

To further support the view that the lysozyme synthesis is *de novo*, RNA was extracted from cells (RNase  $I_{10}^-$ , *su*<sup>-</sup>) infected with the phage mutant *am* H-26 which contains an amber mutation in the structural gene for the phage lyso-

zyme. This RNA, while active for the incorporation of amino-acids, does not stimulate the synthesis of lysozyme (Table 1). The mutant phenotype of *am* H-26 does not seem to include pleiotropic effects on other late messengers, for a normal yield of mature phage can be released from the cells with egg-white lysozyme. Consequently, this result shows that the enzyme activity found in the products of *in vitro* synthesis is specific for the phage lysozyme messenger. RNA extracted after 20 min of infection with mutants in another late gene (*am* H-11 and *am* A-489, both in the structural gene for  $T_4$  head protein, results not shown) is fully active in programming the *in vitro* synthesis of lysozyme activity as expected.

Table 1. AMINO-ACID INCORPORATION AND LYSOZYME ACTIVITY IN PRODUCTS OF *in vitro* PROTEIN SYNTHESIS

RNA added to complete system	Lysozyme activity	$\mu$ Moles of tritiated leucine incorporated/ml./20 min
$T_4$ 20 min RNA	39.3	722
RNA from uninfected cells	3.7	427
$T_4$ 5 min RNA	3.9	625
$T_4$ 20 min RNA from <i>am</i> H-26	2.0	698
$T_4$ 20 min RNA extracted without egg-white lysozyme	30.0	792
$T_4$ 20 min RNA—zero time	3.1	1
No added RNA	2.9	59
$R_{17}$ RNA (300 $\mu$ g/ml.)	2.8	1,420

The final concentration of RNA in the incubation mixture in each case was 400  $\mu$ g/ml. (except  $R_{17}$  RNA). Lysozyme activity was determined from tracings as shown in Fig. 2 by measuring the maximum slope of the decrease in turbidity, and is expressed as the decrease in optical density/min  $\times 1,000$ . The total optical density at time zero of the assay was near 0.4 in each case. The lysozyme activities are from 0.1 ml. of *in vitro* reaction mixture added to 1 ml. of the substrate. Assuming no dilution of the 0.01  $\mu$ mole/ml. of added leucine, 1  $\mu$ mole represents 55 c.p.m. (Leucine in the reaction mixture dilutes this 1.2–1.4-fold.)

Because all the RNA samples (including those from uninfected cells or cells infected for 5 min) used here were extracted with egg-white lysozyme to help open the cells, and because the active RNA samples come from cells making lysozyme, it is possible that the mRNA fractions could be contaminated with lysozyme activity. This is ruled out by the following control experiments. If the  $T_4$  20 min RNA is prepared with the omission of egg-white lysozyme (cells infected for 20 min are sufficiently opened without the enzyme), normal incorporation of amino-acids and lysozyme activity are observed in the *in vitro* system (Table 1). Negligible activity is found if the 20 min RNA preparations are assayed directly for lysozyme (results not shown). At zero time samples for *in vitro* synthesis with  $T_4$  20 min RNA show no activity (Table 1 and Fig. 3).

Fig. 3. Time course of synthesis. The *in vitro* protein synthesis is with  $T_4$  20 min RNA (400  $\mu$ g/ml.). Duplicate 0.1 ml. samples were withdrawn at intervals during the incubation and were assayed for lysozyme activity as in Fig. 2, and for incorporation of tritiated leucine (specific activity 55 c.p.m./ $\mu$ mole, as in Table 1). The lysozyme activity is expressed in terms of the protein in a crude  $T_4$  lysozyme standard used throughout these experiments. This standard was made by infecting *E. coli* RNase  $I_{17}$  with  $T_4$  for 30 min. The cells were collected, ground with alumina and centrifuged for 20 min at 18,000g. The supernatant was frozen in small samples and used to prepare standard curves relating the maximum rate of lysis of the substrate to  $\mu$ g of protein in the extract. The substrate varies from day to day and so a new standard curve is made each day.

Table 2. INHIBITORS OF PROTEIN SYNTHESIS

Additions	Lysozyme activity	$\mu$ Moles of tritiated leucine incorporated/ml./20 min
$T_4$ 20 min RNA +:		
Chloramphenicol, 0.5 mmolar		
Added after protein synthesis	36.3	737
Added before protein synthesis	2.5	3
Puromycin, 1 mmolar		
Added after protein synthesis	35.9	718
Added before protein synthesis	1.6	2
$T_4$ RNase, 5 units		
Added after protein synthesis	39.9	767
Added before protein synthesis	2.2	2
No RNA added	2.9	59

See legend to Table 1. Similar experiments with pancreatic RNase are complicated by the fact that RNase itself causes a decrease in the substrate turbidity (a similar effect has been noted by Brenner<sup>14</sup>). This decrease is small and essentially complete by 5 min in the conditions used. Control experiments showed that lysozyme could be effectively detected by following the drop in turbidity after this time. The results agree with those above: when pancreatic RNase is added before the *in vitro* incubation it prevents synthesis of lysozyme.

Finally, the following experiments using inhibitors of protein synthesis also rule out the possibility of lysozyme activity contaminating the mRNA fractions or the cell free system in general.

Synthesis *de novo* of enzyme activity in a cell free system should be inhibited by any conditions that block protein synthesis. Table 2 shows the results of experiments using chloramphenicol, puromycin and RNase  $T_1$ . Inhibition of incorporation of amino-acids is accompanied by abolition of lysozyme synthesis in each case.

Fig. 3 shows a comparison of the time courses of incorporation of amino-acids and the appearance of lysozyme activity. The kinetics are similar except for a relative decrease in lysozyme synthesis in the later portion of the reaction.

Fig. 4. Dependence on concentration of magnesium. Each point represents the lysozyme activity or radioactivity in a 0.1 ml. sample (see Fig. 3) from an incubation mixture containing  $T_4$  20 min RNA (400  $\mu$ g/ml.) and the indicated concentration of magnesium acetate. Incubation was for 20 min. The specific activity of the leucine was 55 c.p.m./ $\mu$ mole. The 30 min extract used as a standard in these experiments contained, per  $\mu$ g of total protein, lysozyme activity equivalent to 0.131  $\mu$ g of egg-white lysozyme. Purified  $T_4$  lysozyme has 165 times greater specific activity than egg-white lysozyme, as calculated from the data of Terzaghi (PhD thesis, University of Oregon, 1965), using different assay conditions. With this ratio we compute the fraction of protein synthesized *in vitro* that is active  $T_4$  lysozyme. For example, at the magnesium optimum in Fig. 3 (7.5 mmolar) the incorporation of leucine represents 920  $\mu$ mole or about 0.1  $\mu$ g of total amino-acids incorporated/0.1 ml. of reaction mixture (assuming that leucine makes up 10 per cent of the total amino-acids). The lysozyme activity in this 0.1 ml. corresponds to about 0.004  $\mu$ g of  $T_4$  lysozyme (assuming the foregoing ratio of specific activities of  $T_4$  and egg-white lysozymes, and assuming equal specific activities of the *in vitro* and *in vivo* made lysozyme).

The dependence of *in vitro* protein synthesis on the concentration of magnesium is very characteristic and can be used as another criterion for correlating protein and lysozyme synthesis. Magnesium response curves are shown in Fig. 4. Lysozyme synthesis is completely inhibited by concentrations of magnesium which are either too high or too low for efficient incorporation of tritiated leucine. The optimal concentrations of magnesium for total protein synthesis and lysozyme synthesis are the same, but at concentrations greater than optimal, relatively less lysozyme is synthesized. At 11 mmolar magnesium, where incorporation of amino-acids is 50 per cent of the maximum, less than 10 per cent of the maximal lysozyme activity is observed. This decrease in the enzyme activity of the *in vitro* product at high concentrations of magnesium suggests that incorrect initiation or some other decrease in fidelity is occurring. This is consistent with results obtained using synthetic polynucleotides<sup>17-19</sup>.

Finally, there seems to be a good correlation between the relative amounts of lysozyme made *in vitro* and *in vivo*. An approximate calculation (shown in the legend of Fig. 4) suggests that 4 per cent of the total protein made *in vitro* is lysozyme. This is similar to the fraction of late phage specific protein synthesis devoted to lysozyme *in vivo*.

In conclusion, all our evidence suggests that the appearance of lysozyme activity observed in the *in vitro* system has the characteristics of *de novo* synthesis. That is, the synthesis is mRNA specific and is inhibited by chloramphenicol, puromycin and RNase. The incorporation of amino-acids and the appearance of lysozyme activity have similar kinetics and dependence on magnesium. Finally, the inability of RNA from a *T<sub>4</sub>* mutant with an amber mutation in the lysozyme structural gene to stimulate synthesis of lysozyme shows that the activity we measure is that of phage lysozyme.

Perhaps the chief contribution of the work discussed here is that the *in vitro* translation in a well characterized RNA dependent system can be sufficiently accurate to yield active proteins, and that this can be done using

RNA extracted by standard techniques from cells infected by a DNA phage. The assay is dependable and easy, and routinely gives a stimulation at least ten-fold over background, and so it will provide an accurate and convenient assay for biologically meaningful translation.

We thank Sabine Doebring for technical assistance, Alfred Tissières and Richard Epstein for their help and the hospitality of their laboratories, and Pierre F. Spahr, Jim Watson and Eric Terzaghi for advice. This work was supported by a grant from the Fonds National Suisse de la Recherche Scientifique. W. S. was the recipient of a Helen Hay Whitney Foundation post-doctoral fellowship and R. G. of a National Science Foundation post-doctoral fellowship.

## Effect of Antilymphocytic Antibody and Antibody Fragments on Human Lymphocytes *in vitro*

The mode of action of horse anti-lymphocyte serum (IgG) and its pepsin fragments has been investigated by lymphocyte agglutination tests, cytotoxic tests and the uptake of uridine and thymidine. It is found that its divalent pepsin fragment (F(ab')<sub>2</sub>) agglutinates lymphocytes and stimulates the uptake of uridine and thymidine whereas the univalent fragment (Fab') is inactive in all these tests.

THERE have been numerous reports from this<sup>1</sup> and other laboratories describing the immunosuppressive properties of antilymphocyte serum\* (ALS) and its effects on lymphocytes *in vitro*; its mode of action is, however, still obscure, although various theories have been proposed. The present

\* Serum denotes not only serum separated in the usual way from clotted blood but also plasma from which the fibrinogen has been removed by heating (56° C for 30 min) and filtration. ALS denotes any serum having demonstrable effects on lymphocytes *in vivo* or *in vitro* whether raised with injections of intact lymphoid cells (as in the present experiments), intact cells of other types, or cellular fractions.

experiments, which are concerned with the effects of horse-anti-human ALS, serum fractions and antibody fragments on human blood lymphocytes *in vitro*, form part of a systematic study designed to elucidate this question.

ALS in the form of filtered inactivated plasma was prepared from the last two collections of blood obtained from a horse which had received nine injections of intact cells from human infant thymus or adult spleen over a period of about 10 months (see Table 1). Previous investigations<sup>2</sup> showed that IgG and 7S 'Sephadex' fractions

Table 1. SCHEDULE OF IMMUNIZATION OF HORSE

Bleeding, 10 l. on 23-12-1966; 10 l. on 30-12-1966.

\* The thymuses were obtained at routine autopsy (by courtesy of Dr A. D. Bain). One spleen was obtained within 30 min of death and the others were removed in the course of radical gastrectomy for carcinoma of the stomach.

from earlier batches of serum from the same animal contained most of the material responsible for lymphocyte agglutination and cytotoxicity, and for the stimulation of uridine and thymidine uptake by lymphocytes in culture, whereas much of the erythrocyte agglutinin was in the 19S 'Sephadex' fractions and could be absorbed out of whole serum without significantly reducing its lymphocyte agglutinin and cytotoxic titres or its stimulating effect on lymphocytes in culture. In the present experiments, therefore, all preparations in which the erythrocyte agglutinin reciprocal titre exceeded four were absorbed with human erythrocytes to bring the titre below this level before they were tested against lymphocytes. Normal horse and antilymphocytic IgG globulins were prepared by diethylaminoethyl (DEAE) cellulose batch chromatography on Whatman 'DE11' exchanger with an ion exchange capacity of 1.0 m.equiv/g. The products were concentrated by lyophilization and reconstituted to 1 g per cent (w/v) in 0.06 molar phosphate buffer (pH 7.2) containing 0.15 molar sodium chloride. Their purity was checked by immunoelectrophoresis using a rabbit-anti-horse serum and polyacrylamide gel electrophoresis. The antibody preparation contained only small amounts of contaminating protein, probably IgA (T). The F(ab')<sub>2</sub> portion of the IgG molecule, which contains both antigen combining sites, was prepared by digestion in pepsin<sup>3</sup>. The digestion was performed at 37°C for 48 h in 0.1 molar acetate buffer pH 4.0 (using one part enzyme to fifty parts protein by weight). The

products were finally dialysed against the above phosphate buffered saline. Degradation of the IgG preparations to the F(ab')<sub>2</sub> fragment was shown to be complete by immuno-diffusion and, in the case of the antilymphocytic preparation, by subsequent cytotoxic analysis. The univalent Fab' fragment was prepared by reduction of the divalent F(ab')<sub>2</sub> fragment with 0.1 molar cysteine in 0.06 molar phosphate buffer (pH 7.2, containing 0.15 molar sodium chloride) and then alkylated. This was achieved by dialysing the reduced preparations against large volumes of 0.02 molar iodoacetate in the same buffer. The excess iodoacetamide was removed by dialysis for 24 h against three changes of large volumes of phosphate buffer (100 volumes) through which nitrogen was continuously bubbled. This treatment was found to be essential because trace amounts of iodoacetamide (less than 0.0002 molar) were extremely toxic to lymphocytes in culture. Extensive dialysis procedures (greater than 2 days) in the absence of nitrogen resulted in a significant amount of recombination of the Fab' units to the F(ab')<sub>2</sub> fragment. All these preparations were sterilized by 'Millipore' filtration and stored at -20°C.

The IgG globulin content of the sera was determined by quantitative cellulose acetate electrophoresis and by the antibody-agar radial diffusion procedure<sup>4</sup> using a rabbit-anti-horse IgG serum and horse IgG standards. The protein content of the samples was determined by the Folin phenol procedure<sup>5</sup> and in the case of the purified preparations and fragments it was also determined by measuring the extinction coefficient at 280 mμ in a 1 cm cell.

Agglutination and cytotoxic tests were performed as described by Abaza and Woodruff<sup>6</sup> with the following modifications. (a) Lymphocytes were obtained from 400 ml. fresh heparinized human blood by filtering it through a Fenwal 'Leuko-Pak', to remove the polymorphs, and then sedimenting the red cells by adding 120 ml. of 3 per cent gelatine and allowing it to stand for 45 min at 37°C and then for 30 min at room temperature. (b) In both tests the number of viable lymphocytes in each tube or well was four million. (c) Rabbit complement was used instead of guinea-pig complement in the cytotoxic test. With rabbit complement a higher value is

\* The dose per culture of serum and serum derivatives contained 2.0 mg IgG or fraction. The dose per culture of PHA was 0.1 ml. reconstituted dried phytohaemagglutinin (Wellcome).

† Figures on the same horizontal line relate to replicate cultures set up at the same time with cells from the same donor.

obtained for the titre and, what is more important, the end point is sharper. (d) The final serum dilutions were adjusted according to the concentration of IgG or antibody fragment in the preparation so that the first tube or well contained approximately 1 mg IgG or fragment in a total volume of 0.4 ml. This is referred to as a dilution of 1:4 because our standard preparation of IgG contains 1 mg/0.1 ml. On this basis the reciprocal lymphocyte agglutinin titres of antilymphocytic serum, IgG and F(ab')<sub>2</sub> were essentially the same and ranged from 1024 to 4096 in tests performed with lymphocytes from various donors. The Fab', on the other hand, had a negligible titre (titre<sup>-1</sup> ≤ 4). The cytotoxic titre<sup>-1</sup> (with rabbit complement) was 1024 for antilymphocytic serum and IgG, and negligible for both fragments (≤ 4). The agglutinin and cytotoxic titres of normal horse serum, and of IgG and fragments derived from it, were negligible (titre<sup>-1</sup> < 4).

Lymphocyte cultures were set up in Bijoux bottles and incubated at 37°C. Each culture initially contained about 10 million viable lymphocytes and 10–20 million erythrocytes in 2 ml. medium 199 plus 0.5 ml. autologous plasma. Usually the plasma was inactivated by heating (56°C for 30 min), but in experiments designed to study the effect of complement unheated plasma was used. The various preparations to be tested for stimulating activity were added as described here. Some cultures were set aside for morphological study, but the majority were used to study the incorporation of tritiated uridine or thymidine. Tritiated uridine (specific activity 2.73 c./mmole) was added when the cultures were set up, and tritiated thymidine (specific activity 5 c./mmole) was added to cultures which had been incubated for 72 h. In each case the final concentration of isotope was 1.67 µc./ml. Eighteen hours after the addition of tritiated uridine, or 24 h after the addition of tritiated thymidine, the cells were spun down and washed three times in phosphate buffered saline and then successively in 5 per cent trichloroacetic acid, phosphate buffered saline, and absolute methanol. After the final spin the supernatant was discarded and the precipitate was taken up in the minimum possible quantity of hyamine hydrogen chloride and heated for a few minutes in a water bath at 60°C. After cooling, 10 ml. of scintillant (NE 213, Nuclear Enterprises, Edinburgh) was added and counting was performed with a Packard 'Tricarb' scintillometer. Cultures were set up usually in triplicate (occasionally duplicate or quadruplicate). The counts per minute in control cultures which contained only cells, medium 199 and autologous plasma showed not more than 25 per cent variation from the mean value (and often much less than this) when each contained cells from the same donor, but the mean c.p.m. in control cultures of cells from different donors ranged from 17,520 to 81,600 (fourteen donors; mean 46,250 ± 21,800) in cultures incorporating tritiated uridine, and from 6,400 to 44,430 (four donors; mean 19,930 ± 12,790) in cultures incorporating tritiated thymidine. It has seemed desirable therefore to calculate for each treated culture the relative count, that is, the ratio of

Fig. 1. Curve showing relationship between the degree of stimulation of uridine uptake (expressed as mean relative count) and the amount of ALS added to the culture. Based on experiments using the same serum but lymphocytes from six different donors.

c.p.m. in that culture to the mean c.p.m. of the control cultures set up at the same time with cells from the same donor.

The results of tests with a standard dose of each of the various preparations are summarized in Table 2, from which it will be seen that antilymphocytic serum, IgG and F(ab')<sub>2</sub> were all highly active in stimulating uptake of both uridine and thymidine, and when given in comparable dosage to the same donor all produced approximately the same degree of stimulation. Initial experiments with Fab' were invalid because the preparation contained toxic amounts of iodoacetamide, but the preparation referred to in Table 2, which had no stimulating effect, was non-toxic as shown by the trypan blue test and by the fact that a preparation made in the same way from normal horse serum did not depress the uptake of uridine.

In the absence of complement, stimulation of the uptake of uridine is, within the limits of the experiment, an increasing function of the amount of antilymphocytic antibody added to the culture. The dose response curve is shown in Fig. 1. The effect of complement is shown in Fig. 2. When the lymphocytes were suspended in medium 199, and ALS and complement (in the form of raw autologous plasma) were added later, there was extensive cytolysis, and stimulation of uridine uptake was completely inhibited (Fig. 2a). When, on the other hand, the cells were suspended in a mixture of medium 199 and autologous plasma, and ALS was added 30 min or so after the suspension had been prepared, the degree of inhibition was very much less (Fig. 2b). These results confirm in a slightly different system some recent observa-

Table 3. EFFECT OF TIME OF EXPOSURE TO STIMULATING AGENT AND PRE-TREATMENT WITH Fab' ON UPTAKE OF <sup>3</sup>H URIDINE BY HUMAN LYMPHOCYTE CULTURES

Stimulating agent	Pre-treatment				Relative count	Mean
Agent and dosage	Duration of exposure	Agent and dosage	Duration of exposure	Cell donor	Observed	
ALS (0.2 mg IgG)	18 h	Nil		G	11.0, 7.50	9.27
		Fab' from ALS	15 min	G	4.65, 7.59, 3.04	5.09
	1 h	Fab' from NHS	15 min	G	4.62, 5.85, 10.2	6.89
		Nil		H	4.91, 4.96, 5.65	5.17
		Fab' from ALS	15 min	H	10.8, 11.2, 17.4	13.1
		Fab' from NHS	15 min	H	14.4, 13.3, 14.9	14.2
	15 min	Nil		H	1.94, 1.91, 1.75	1.87
		Fab' from ALS	15 min	H	2.70, 2.89, 2.29	2.62
		Fab' from NHS	15 min	H	2.52, 2.27	2.40
PHA (0.1 ml.)	18 h	Nil		G	11.0, 8.90	9.95
		Fab' from ALS	15 min	G	8.86, 8.76	8.80
	15 min	Fab' from NHS	15 min	G	17.0, 10.5	13.7

tions of Holt, Ling and Stanworth<sup>7</sup>. As would be expected, complement caused little, if any inhibition of the stimulating effect of  $F(ab')_2$ . Thus the ratio

Mean relative count in cultures with complement

Mean relative count in cultures without complement

for cultures containing  $0.2 \mu\text{g } F(ab')_2$  was 0.80 and 0.92 in two separate experiments, and these figures do not differ significantly from the ratios observed in untreated control cultures which, for some unknown reason, consistently showed a somewhat lower count when raw autologous plasma was used instead of inactivated plasma (Fig. 2).

Fig. 2. Effect of complement on uridine uptake at different ALS concentrations. ○, Without complement; ×, with human complement. (a) 2.0 ml. of a suspension of lymphocytes (donor E) in medium 199 was put in each culture bottle. ALS and either raw or inactivated autologous plasma was added later, followed by tritiated uridine. Counting was done after 18 h. (b) 2.5 ml. of a suspension of lymphocytes (donor I) in a mixture of medium 199 (four parts) and raw or inactivated autologous plasma (one part) was placed in each culture bottle. About 30 min after the suspension had been prepared ALS and tritiated uridine were added. Counting was done after 18 h.

Experiments in which lymphocytes were exposed to stimulating agents for short periods of time and then twice washed before being put up in culture (Table 3) showed that exposure to ALS for 15 min results in only very slight stimulation, and exposure for 60 min to less than maximal stimulation, whereas exposure to phytohaemagglutinin (PHA) for 15 min is as effective as exposure throughout the 18 h of culture.

Pre-treatment of lymphocytes by exposing them for 15 min to  $Fab'$  prepared from ALS, followed by two washes, did not significantly block the stimulation of the uptake of uridine by subsequent exposure to ALS (Table 3); indeed when the exposure to ALS was limited to 60 min, uptake appeared to be increased by pre-treatment with  $Fab'$  from either ALS or normal serum. On the other hand, there is a suggestion that the stimulating effect of PHA is to some extent inhibited by pre-treatment with antilymphocytic  $Fab'$  though not with  $Fab'$  from normal serum. The significance of these observations is difficult to assess because we do not know for how long  $Fab'$  remains attached to the surface of the lymphocyte. It should be possible to answer this question by using either the Coombs test or immunofluorescence, and experiments of this kind are being undertaken.

As we have seen, antilymphocytic serum and IgG stimulate the uptake of uridine and thymidine by lymphocytes in the absence of complement, but when complement is present they fail to do so, and at high concentration cause cell lysis. This suggests that the action of ALS *in vivo* may depend on such factors as the local concentration of antibody and complement, and the degree of anti-complementary activity, in lymphoid tissue and also in the blood stream.

It is noteworthy that  $F(ab')_2$  is as effective as IgG not only in respect of lymphocyte agglutination but also in respect of the stimulation of uptake of uridine and thymidine.

Clearly it will be of great interest to determine the effect of  $F(ab')_2$  on the blood lymphocyte count and also on immunological responsiveness *in vivo*. This cannot readily be determined in man, but experiments with  $F(ab')_2$  from horse-anti-rat ALS are in progress. The most likely explanation of the failure of  $Fab'$  to block subsequent stimulation by ALS or IgG would seem to be that the  $Fab'$  does not become firmly attached to combining sites on the surface of the lymphocyte. Alternatively, it is possible that a "homoreactant" phenomenon<sup>8</sup> is operative. If this is so, intact antilymphocytic IgG or normal IgG would be capable of agglutinating  $Fab'$  coated cells and thus possibly causing transformation. The question of whether ALS and PHA attach to the same receptors, which we had hoped to be able to answer, remains open.

We thank Mr J. G. Watt for injecting and bleeding the horse, and for assistance in preparing the serum; Dr A. D. Bain and Mr Andrew Logan for obtaining some of the human tissue used for immunization; and Drs P. Tothill and D. C. Simpson of the Department of Medical Physics for much helpful advice and for making the liquid scintillation counter available to us. Dr Reid is on sabbatical leave from the University of Sydney and is indebted to the Royal Society for a travel grant.

# Vision in Monkeys after Removal of the Striate Cortex

by  
N. K. HUMPHREY\*  
L. WEISKRANTZ\*

Psychological Laboratory,  
University of Cambridge

Monkeys deprived of their visual cortex (area 17) have been thought to be unable to discriminate much more than "total luminous energy". In particular, they have been considered incapable of localizing visual events in space. It has now been shown that they can be trained to detect and accurately reach out for objects of certain kinds presented visually.

TOTAL removal of the striate cortex in monkeys results in a loss of vision so severe that in their ordinary behaviour the animals seem blind. In formal testing situations, however, it has been possible to demonstrate a certain degree of visual capacity: pupil responses to light are still present; opto-kinetic nystagmus elicited by a large field of moving stripes is present, at least some months after surgery<sup>1,2</sup>; in addition, performance may be good on certain kinds of visual discrimination. Kluver, in a series of classic papers<sup>3</sup>, analysed the visual discrimination capacity of the de-striate monkey as an ability to discriminate "total luminous energy". More recently Weiskrantz<sup>4</sup> has shown that some discriminations are possible even when the discriminanda are matched for luminous flux and has suggested that there is an ability to discriminate "total retinal activity"—contour length, movement and flicker contributing besides luminous flux. There has been general agreement, however, that spatial information is no longer available: the lesion eliminates "visual space with its dimensions"<sup>5</sup>. We wish to report here new observations on two de-striate monkeys which show that they can not only detect but accurately locate certain objects by vision.

The subjects were two adolescent rhesus monkeys. Bilateral total removal of striate cortex was carried out under 'Nembutal' anaesthesia by occipital lobectomy followed by aspiration of the striate tissue remaining on the lateral surface and in the depths of the calcarine fissure. Histological verification of the lesions has not yet been made because the animals are still alive awaiting the completion of subsequent experiments.

The observations were made about 19 months and 5 months, respectively, after surgery. During the previous months both monkeys had been tested on various kinds of visual discrimination<sup>4</sup> and had reached a good level of performance on some of the problems. These discriminations included brightness problems, for example, black versus white, and elementary pattern problems, for example, black and white stripes versus homogeneous grey (matched for total luminous flux), but the visual capacity revealed could be interpreted in terms of discrimination of total retinal activity and required no supposition of spatial discrimination. In addition, the monkeys had been tested in a nystagmus drum and showed clear opto-kinetic nystagmus; they also showed good pupil responses. Apart from this evidence they had given almost no sign of visually guided behaviour.

A surprising fact had, however, been noticed: the monkeys occasionally turned their heads or eyes in the direction of a moving object. We were inclined at first to attribute this to an acute sound sense or an ability to detect movements of air. Further observation convinced us, however, that the response was genuinely based on vision and we were led to examine it more carefully. Within a few days we were able to demonstrate a quite unexpected visual capacity.

Both monkeys showed similar development of visually guided performance and a case history of one (monkey Hln, 19 months post-surgery) can serve to describe the testing method and results. Testing was carried out

in the home living cage, fitted with a 2 ft. × 2.5 ft. front of 2.5-in. wire mesh. The first stage was to train the monkey to reach through the mesh to find a morsel of food (a nut or piece of fruit) which was held out to him by the experimenter. The requirement was that he should search the field by reaching from one place to another until he made contact with the experimenter's hand holding the food. This training was accomplished by a simple process of shaping in which at first the experimenter deliberately moved his hand to whatever position the monkey happened to reach and then progressively required him to reach closer and closer to his hand before rewarding him. Within a short time the monkey learned to find the experimenter's hand in any part of the field by a series of exploratory reaches. The next stage was to try to help him in his search by visual cues.

It was soon clear that when the experimenter held his hand stationary the monkey had no idea where it was and reached at random. If, however, the hand was moved, by waving it gently or wagging a finger, he did have some idea of its location and reached at once in roughly the right direction. It seemed at first that his ability to localize was very poor, but with practice he got better and better. Eventually he could reach for the hand promptly and accurately as soon as it moved; but while it was stationary he still appeared quite blind. To ensure that his ability to locate movement was not based on non-visual cues, he was tested in darkness, whereon his performance dropped to a chance level.

A man's hand at monkey's arm's length is a rather big target and the accuracy of reaching had not yet been tested to its limit; moreover, the effective stimuli had not been well defined. Further testing was therefore undertaken more systematically. Observation so far had shown that the response of reaching to touch a perceived object was a simple and seemingly natural response for the "blind" monkey; it had the advantage also that it was self-correcting because success or error in locating the object was immediately signalled by touch. This response was therefore retained as the index of vision. Instead of the experimenter's hand, the objects to be detected were 1-in. square wooden blocks held by the experimenter on the ends of wire sticks. Different visual stimuli could be attached to or painted on these blocks and they could be held stationary or moved. The monkey was required to reach out and grasp the block. Success was rewarded by a morsel of food put directly into his hand which he held out expectantly after letting go of the block. With this procedure, the following visual ability has been demonstrated.

*Detection of a moving object.* The monkey is extremely sensitive to moving objects of all kinds. In a typical case, he will reach out to grasp with a sure hand a 1-in. black cube which is waved very slightly at arm's length from him. His sensitivity is so acute that it is hard to hold objects still enough to prevent him detecting their tremor. Speed of movement, over a wide range, seems not to matter. All sizes and shapes of objects from a 0.25 in. cube to a long straight bar are detectable, although with large objects he tends to reach for one edge. The objects can be lighter or darker than the background. The absolute level of illumination may be varied over the

\* Present address: Institute of Experimental Psychology, University of Oxford.

whole range over which a human observer can easily see; he has, for instance, performed well both in a very dimly lit room and under very bright illumination while a film was being made.

For most routine testing the stimulus object has been a 1 in. cube painted with black and white stripes. In order to avoid ambiguity concerning where the monkey should reach to, the movement given to it is rotation about its centre rather than change in position. When the monkey sees the object he usually shows an obvious expression of recognition (an "aha!" reaction) and turns his eyes towards it before reaching. He is best at detecting the object if it is presented near the centre of his visual field and will often miss it in the peripheral field; rough observation suggests that he gets very inefficient about 40° out from the centre. He is equally good in all quadrants of the field. He does not appear to be able to discriminate distance and if the object is presented nearer or farther away than the standard arm's length he over- or under-reaches; he will, for instance, reach forlornly for a moving object 6 ft. away. It is not necessary for movement of the object to be kept up until he reaches for it or even until he has had time to fixate it; he can detect and locate a sudden sharp movement. He can remember the location of an object after it has stopped moving and if, for instance, he has his hands full of food or is otherwise occupied when the object is moved he may defer reaching for several seconds but then reach accurately. If translational movement is used rather than simple rotation, he can often reach accurately for an object which has moved and come to a stop, although he may sometimes reach to a point along the object's path rather than its terminal position. He does not, however, seem to be able to track a moving object and is unlikely to reach accurately for it while it is still moving along; this inability is paralleled by his apparent failure to follow a moving object with his eyes.

*Detection of a stationary object.* The monkey never detects a stationary black or white painted cube. This is so even though he may search actively with his eyes and thus cause the image of the object to move over his retina. He cannot reliably detect a stationary neon light in ordinary room illumination, although occasionally he does reach for it with surprising accuracy. If the background illumination is reduced, however, he does become able to detect the light, and in darkness can locate it well. With a light of 1.5 log foot lamberts his performance becomes good below about 2.7 log foot lamberts background illumination. No systematic observations have been made on eye movements or the relative efficiency of different parts of his visual field here because it is difficult for the experimenter to see.

*Detection of light flashes.* The monkey can detect and locate a flashing neon light in either room illumination or darkness. He is very sensitive to flash rates of about 10 per sec (flash duration 5 msec). As the flash rate is increased he remains good until about 45 per sec, but is unable to detect rates beyond 55 per sec. This threshold corresponds very closely to the critical flicker fusion frequency for a human observer. If the flash rate is initially high, say 100 per sec, so that the light appears stable, and is then progressively lowered, he detects the light at about the point where it begins to flicker for a human observer. He can detect slow flash rates down to single isolated flashes, although he does have more trouble in locating the latter. With slow rates of about 1 flash per 4 sec he does not reach after the first flash but turns his eyes towards it and waits for the next flash to occur in nearly central vision before reaching. With single isolated flashes where he can get no further information by waiting he tends to reach rather tentatively, although often quite accurately, unless the flash happens to occur close to where he is already looking, in which case he is more confident. As with detection of movement, he is much less efficient in the peripheral than in the central field.

*Detection of two objects presented together.* To test further the monkey's ability to localize objects in space, an attempt was made to train him to respond to two objects presented simultaneously in different positions. The objects were held out as before and he was required to grasp one and then the other in sequence to get a reward. Pairs of rotating 1-in. cubes or flashing neon lights were used. They were presented in random spatial relationship to each other.

The monkey very quickly caught on to the procedure. He can perform well with both kinds of stimuli. He is best when the objects are fairly widely spaced, about 10 in. apart, but can also do well with them closer together; when they are less than about 3 in. apart, however, he sometimes reaches for the same object twice or occasionally reaches between them. The relative spatial orientation of the two objects does not matter and he is just as good at locating two objects one above the other as two objects side by side. This capacity provides him with the basis for simple spatial pattern discrimination: for instance, he clearly discriminates a horizontal from a vertical relationship when he responds appropriately to objects presented in the two ways. He nearly always fixates each object before reaching for it, although he does not have to. With moving objects, the movement does not have to be kept up until he reaches and he can accurately locate two objects which are given only a sudden rotational jerk; he has not, however, shown much ability to locate two single light flashes.

Two general features of the monkey's performance are of interest. One is that he performs well only when he attends to what he is doing. If he is over-excited or distracted by some commotion outside his cage his performance breaks down and he tends to reach wildly. Although this may seem obvious, it would not in fact be typical of a normal monkey performing the same task. The other feature is that he sometimes shows "false positive" responses, reaching apparently purposively to an empty part of the field. Together, these observations suggest that he is working not far beyond the threshold of his capacity and that he may mistake internal "noise" for an external stimulus.

The other monkey in the group (monkey Hmr, 5 months post-surgery) has showed a similar ability to detect both moving objects and stable and flashing lights. His performance at best is as good as that of the monkey just described. He has, however, developed a bad habit of swiping for the object instead of reaching straight to it. He also shows rather more false positives than the other monkey. In general he appears less eager to be tested and tries less hard.

The most conservative explanation of these results would be that the striate cortex has not been removed completely in either monkey. The removal of the last vestige of striate tissue from the depths of the calcarine fissure is surgically difficult and the possibility of incomplete removal cannot be discounted until histological verification of the lesions is made. Allowing, however, that this may be so, there is good reason to doubt that it would be an adequate explanation of the results. First, any remaining striate tissue must lie in an area serving a small part of the far periphery of the visual field; but the monkeys are consistently better at locating objects near the centre of the field; they fixate objects with central vision, they can locate two objects at once in different parts, and they show no bias towards any quadrant of the field. Second, Cowey and Weiskrantz<sup>5</sup>, using a method of perimetry with monkeys that accurately controls for eye movements, have shown that after striate lesions there is an ability to detect light flashes over the whole of the affected area of the field which certainly does not depend on remaining striate tissue. Although their study did not bear on the ability to localize flashes, the clear demonstration of the possibility of extra-striate vision makes it easier to accept the present results without special pleading.

The most striking feature of the present study is the evidence for spatial localization by the de-striate monkey. Similar findings have never been reported in detail, although Pasik, Pasik and Krieger<sup>6</sup> say that, some months after surgery, their de-striate monkeys "followed large white targets and grasped at a source of light". When compared with evidence for other species, however, the results may be thought less surprising. In lower mammals there are several reports of the existence of considerable visual capacity after removal of striate cortex, in particular an ability to discriminate moving from stationary objects (reviewed by Weiskrantz<sup>7</sup>). Especially notable is the recent study of the tree shrew<sup>8</sup> where striate ablation was found to have no obvious effect on visually guided behaviour. In the cat it has been reported that striate ablation soon after birth may have little effect on the subsequent development of vision<sup>9</sup>. But in man also there are reports in the clinical literature of cases of cortical "blindness" after damage to the striate area where residual vision existed in the affected fields. Riddoch<sup>10</sup> describes several cases showing ability to perceive movement within perimetrically blind fields. He says, "The patients have great difficulty in describing the nature of the movement they see: it is so vague and shadowy. But they are quite sure that neither shape nor colour can be attributed to it, and that it can be detected in a field which is entirely blind to stationary objects". Describing a similar case, Holmes<sup>11</sup> says, "only large white moving objects may be recognized . . . when they cease to move he sees them no longer; they disappear". Bender and Krieger<sup>12</sup> report cases showing an ability to perceive and localize movement and also an ability to see a flickering light or a stable light under conditions of otherwise total darkness. They mention that the perceptions were often unstable and that sometimes illusory movement was seen. Denny-Brown<sup>13</sup> reports a patient with complete hemianopia who could perceive small moving objects in the blind half of the field. He comments that self-induced head movements did not help the patient to see an object if it was stationary. In few of these clinical cases, however, has there been adequate post-mortem verification of the extent of damage to striate cortex. Perhaps for this reason, the possibility of extra-striate vision in man has received little acknowledgment.

The question remains as to what nervous structure may mediate the residual vision after striate lesions. The obvious candidate is the superior colliculus. We have recently made electrophysiological recordings from single

units in the superior colliculus of monkeys and the response properties of these units are in fact well suited to underlie the visual behaviour described in this study. It would, however, be disingenuous to press an analogy between single unit responses and behaviour when a direct method for testing the hypothesis is available. We hope, therefore, soon to study the effects of making collicular lesions in our two de-striate monkeys.

*Note added in proof* (July 4, 1967). Since this paper was submitted, further work with the same animals has revealed a degree of visual capacity beyond that described. With more extensive training there has plainly been a progressive change in the limits to what the animals can see. Monkey Hln has developed an ability to locate stationary lights at much lower contrast levels than those given above: he can now respond to even a dim pea-bulb in room illumination, although he remains apparently quite unable to detect objects darker than the background. The other monkey, Hmr, who has become more willing to be tested, has shown a still more surprising development: he can now respond reliably to almost any small stationary object in room illumination, whether lighter or darker than the background. Both monkeys still apparently find the task of detecting stationary objects relatively hard compared with, say, moving objects. The impression is that they have central tunnel vision for stationary objects. They look from one place to another until, as though by chance, the object falls near the central field and then they may stare fixedly at it before reaching; when they do reach, their accuracy is as good as with moving objects. In view of these new results we should say that we cannot be confident that we have even yet demonstrated the full potential for vision of these animals.

## Cutaneous Receptive Fields of Single Nerve Cells in the Thalamus of the Cat

by  
G. GORDON  
J. R. MANSON

Laboratory of Physiology,  
University of Oxford

This article describes some new receptive properties of cells in the nucleus ventralis posterolateralis. It is shown that the nucleus contains mechanoreceptive cells with excitatory or inhibitory thermoreceptive influences on them, that the observation of surround inhibition in this nucleus depends in part on the type of anaesthesia used, and that some of the cells have directional sensitivity.

THE study of the receptive fields of single cells in the various nuclei of sensory systems has been valuable in understanding the transformations used by these nuclei in the analysis of sensory information. In the sensory systems of the skin, receptive field is usually defined as the area of skin from which natural stimuli, thermal or mechanical, cause excitation of the cell. In anaesthetized cats, we have investigated cells in that part of the thalamus

(the main core of the nucleus ventralis posterolateralis) which receives the main output of the dorsal column nuclei, where analytical transformation defined in a semi-quantitative way by previous experiments<sup>1</sup> has already occurred. This region projects in turn to the cerebral cortex. The position of the tungsten recording electrodes was checked histologically, and the position of many cells marked by electrolytic lesions.

The cells are arranged in a somatotopic fashion; and the region studied was chiefly that for the forelimb. Their receptive fields were almost all on the opposite forelimb. Of some 150 cells of which the fields were adequately investigated, only three had fields on the ipsilateral forelimb: these lay among cells with contralateral forelimb fields, and two of them were shown to lie rather rostrally in the nucleus. The great majority of cells had purely mechanoreceptive fields, responding to bending hairs, to sustained light pressure on the skin or to light mechanical stimuli applied to the pads; some showed a combination of hair sensitivity with pad or skin pressure sensitivity. This agrees with previous investigations of this region of the thalamus<sup>2,3</sup>.

Thermal stimuli were regularly used in testing receptive fields, usually by applying radiant heat and sometimes by warming or cooling with thermoelectric devices in contact with the skin, temperature of the contact element being determined with thermocouples. No cells were found which were sensitive to small changes of temperature within the range 15°–45° C in which peripheral thermoreceptors are known to respond<sup>4</sup>. Cells with sensitive thermoreceptive properties have been found in n. ventralis posteromedialis responding to stimuli applied to the tongue<sup>5</sup>; but the thermoreceptive limb afferents of the cat are unmyelinated<sup>4</sup> and may project in a more complex system of small fibres and cells not resolved by present methods. Two types of cell were regularly found, however, which responded to more intense thermal stimulation: they formed a small proportion (about 10 per cent) of cells of which the fields were adequately studied. These cells had sensitive mechanoreceptive fields on one or more of the pads. In the more common of the two types, characterized in all but one case by an additional hair-sensitive region adjacent to the pads, a thermal stimulus above a reproducible threshold in the range 45°–61° C caused a prolonged repetitive discharge outlasting the stimulus by some seconds. Such cells differ in several ways from those described by Perl and Whitlock<sup>6</sup> as sensitive to noxious stimuli, particularly in their low mechanical threshold. In the other type, characterized by lack of any hair-sensitive region adjacent to the pads, removal of a thermal stimulus of similar magnitude, if above a critical thermal threshold, was followed by an intense discharge of impulses. A later application of heat during the period of intense discharge consistently reduced or stopped this discharge, removal of this subsequent stimulus causing a further surge of intense discharge. Although the functional significance of this sort of thermoreceptive property in cells which also have sensitive mechanoreceptive properties is not clear, these findings suggest that this part of the nucleus has other inputs than from the dorsal column nuclei, in which this kind of thermoreceptive response has not so far been recognized. There are reasons for believing that these properties are not simply due to the two sorts of stimulus exciting the same type of receptor. For example, it was found that a small additional dose of anaesthetic completely abolished the thermal response of one cell of the first type, the cell retaining unimpaired its original slowly adapting mechanoreceptive properties. We also found that the mechanoreceptive properties of the cells which gave thermal responses were not apparently changed by repeated applications of a thermal stimulus which reached threshold for excitation, each mechanical test being made immediately after a thermal stimulus.

The mechanoreceptive fields of a large proportion of the cells projecting to the thalamus from the dorsal column nuclei have been shown to have an inner excitatory zone more or less surrounded by an outer inhibitory zone<sup>1</sup>, and it is thought that this mutual antagonism increases spatial contrast in this system as in the visual system. These fields with surround inhibition seem to be fairly stable under experimental conditions and this pattern is not abolished under moderately deep anaesthesia, for ex-

ample with barbiturates. In n. ventralis posterolateralis, on the other hand, to which these cells project, surround inhibition has been observed less regularly: Poggio and Mountcastle<sup>7</sup>, for example, found it in only 5 per cent of cutaneous cells in this region of the thalamus of the unanaesthetized monkey. The experiments of Nakahama *et al.*<sup>3</sup> suggest a higher incidence of surround inhibition in this nucleus in the cat anaesthetized with pentobarbitone sodium (see their Table 1). With this anaesthetic we found surround inhibition in only 10 per cent of thalamic cells of which the skin fields were adequately studied, averaged over all experiments. But in particular experiments a much higher incidence was found (up to 35 per cent), whereas in many experiments it was not seen at all. One possible reason for simple surround effects not being seen is that the receptive fields have become more complex than those of cells in the dorsal column nuclei. We are inclined to discard this explanation, because under conditions where inhibition was not observed, clear-cut static excitatory fields were seen which gave no indication of specificity with respect to orientation or direction of movement of the stimulus. A second and more general possibility is that in many experimental animals, because of the type or level of anaesthesia, a disturbance in the balance of excitatory and inhibitory actions in the various mechanisms acting on the thalamus leads to the surround inhibition transferred from the dorsal column nuclei being concealed. Some support is given to this by the fact that we have seen surround inhibition consistently with chloralose anaesthesia, in 47 per cent of all cells studied under this anaesthetic. Lighter anaesthesia with short-acting barbiturates (hexobarbitone or thiopentone) did not provide favourable conditions.

Most of the cells in the thalamus which had an inhibitory surround to an excitatory cutaneous field had receptive characteristics similar to those found for such cells in the dorsal column nuclei<sup>1</sup>. Most of those studied were hair-sensitive, usually with small excitatory fields particularly on the forepaw. Such cells did not show any preference for stimuli of specific orientation or direction of movement; though the summation occurring when the stimulus moves does cause rapidly adapting hair-sensitive or pad-sensitive cells to discharge more impulses, giving a preference for moving stimuli which is directionally unspecific, within the confines of the field defined with static stimuli. One pad-sensitive cell, for example, often fired only a single impulse on application of a static stimulus, but fired a high-frequency train of impulses for as long as the stimulating instrument was drawn lightly across the pad in any direction.

Some cells responding to light pressure on the skin with a slowly adapting discharge do, however, have more complex receptive fields. Cells with these characteristics ('touch-pressure' cells) are known to project to the thalamus from the dorsal column nuclei<sup>1</sup> and, in much smaller numbers, from the lateral cervical nucleus<sup>8</sup>; but no inhibitory surround effects have been seen on cells of this type in these nuclei<sup>1,9</sup>. We have found, in agreement with Nakahama *et al.*<sup>3</sup>, that an inhibitory surround, also activated by sustained light pressure, may occur in the thalamus; and this presumably depends on an intrathalamic mechanism. With a number of touch-pressure cells, we have suspected that the field for moving stimuli differed from that for static stimuli, with a preference for one direction of movement; but there was often uncertainty, either because the cell was lost after too short a period of observation, or because of the possibility of artefacts introduced by the method of testing—for example, the situation may be complicated by a moving pressure stimulus exciting receptors at a distance by stretching the skin. Only two such cells were observed for long enough to allow definite conclusions about their fields. The use of moving stimuli elicited responses which could not have been predicted merely from a knowledge of the static field. The field (meaning here the whole area

from which either excitatory or inhibitory effects were produced) became larger, and the regions which were purely excitatory or inhibitory for static stimuli were no longer specific in this way, the borders of the static excitatory zone having to a large extent lost their identity. With one cell, for example, very light pressure applied by a finger moving at about 3 cm/sec in a proximal direction, and starting in the static excitatory zone, caused excitation in the static inhibitory zone further up the arm, whereas stimuli moving distally through this distance into and across the static excitatory field caused inhibition of resting discharge. Both cells that were well investigated showed this type of directional sensitivity with stimuli moving in the long axis of the limb. The dynamic fields tended to vary in extent and sensitivity with time. It appears that these more complex fields represent a stage in the analysis of the direction of movement of stimuli in light contact with the skin.

We thank the Medical Research Council for a grant to G. G. and the Wellcome Trust for a scholarship to J. M.

University of Oxford

Injection of *Mycobacterium leprae* has produced leprosy in mice previously thymectomized and given 900 r. of whole body irradiation to depress their immunological capacity.

LEPROSY is the result of infection by *Mycobacterium leprae*—bacilli which are closely related to those responsible for tuberculosis. *Myco. leprae*, however, unlike *Myco. tuberculosis*, cannot as yet be grown *in vitro*, and to such a limited extent *in vivo* that progress in the aetiology and treatment of the disease is making little headway. This is frustrating, because *Myco. leprae* was one of the first bacteria to have been linked with specific disease in man and yet leprosy has remained a serious world health problem because it gives rise to disabilities and deformities which place a heavy financial burden on society.

An infection can be produced in the foot pads and ears of mice and some other rodents inoculated locally with *Myco. leprae* from patients with leprosy<sup>1-4</sup>. The infection remains localized and multiplication is very small; for example, if  $10^4$  organisms are injected about  $10^6$  can be recovered in 8 months, but if  $10^6$  or more are injected no more than the equivalent of the initial number can be recovered in 8 months. The number of bacilli which can be recovered declines after 8 months and the proportion of degenerate (non-viable) forms increases, but the yield increases again and reaches a second peak at about 13 months, which may be greater than that at 8 months but very rarely exceeds  $10^7$ . After this the number which can be recovered again declines, with a proportionate increase in the number of non-viable forms. Needless to say, the lesion is microscopic and serial sections have to be cut from the ear or foot pad before the colonized zone is found. Its appearance is quite different from any seen in patients with leprosy. The animals, as might be expected, appear to be unaffected as the result of this infection throughout their life span.

Patients with leprosy show many symptoms and signs ranging between two extremes: self limiting tuberculoid leprosy with few bacilli and diffuse lepromatous leprosy with many bacilli. The clinical form which the disease presents seems, therefore, to depend either on the number of organisms which have invaded (size of dose) or on the

patient's capacity (immunological) to combat the infection. The infection in mice is certainly not related to the number of organisms injected so that it seemed reasonable to investigate the effects of reducing their immunological capacity. Two series of mice were thymectomized and given total body irradiation, 900 r., because this is known to have a strong depressive effect on other immunological processes, such as the homograft reaction and antibody production. This resulted in a dramatically greater yield of bacilli from the foot pads in both series<sup>5,6</sup>. Further large scale experiments have confirmed that thymectomy and irradiation with 900 r. results in a greatly increased yield of bacilli after injection of suspensions of  $10^4$  into the hind foot pads and ears of mice. Moreover, inocula of  $10^6$  and  $10^8$  also multiply freely.

These observations were encouraging. Even more encouraging was the unexpected observation that 12 months after inoculation, not only had the local infection increased in intensity but specific sites elsewhere in the body had become infected—for example, the nose and forepaws. Furthermore, the infected foot pads in some of the animals became swollen and the overlying skin was covered with small nodules. In short, the animals appeared to be presenting the image of human leprosy. The spread of infection to specific body sites was particularly noteworthy. This phenomenon prompted us to see whether a systemic infection would follow the intravenous injection of a suspension of bacilli. This route had never led to infections in normal mice; but in the thymectomized and irradiated mice 10 months after injection, bacilli were found in the ears and foot pad, and 19 months after injection nearly a thousand times more organisms could be recovered than had been injected and 95 per cent of these were in the ears, nose and foot pads.

The bacteriological changes already described were paralleled by histological changes in the thymectomized mice given 900 r. These were very interesting, for colonies first started to grow in voluntary muscle fibres as in the

Fig. 1. Growth curves of *Myco. leprae* in skin sites of normal mice (A) and thymectomized and irradiated (with 900 r.) mice (B) injected with  $10^4$  bacilli. Each point represents the mean of counts from both ears and both hind foot pads. ●—●, Total count; ×—×, "viable" count.

case of normal mice<sup>7</sup>, but they gradually disseminated and colonized other cells until months after infection the histopathological picture in the ears, foot pads and cutaneous nerves was comparable in all respects with that in skin and cutaneous nerves of patients with lepromatous leprosy.

The form and nature of the experiments in support of these claims are outlined in Table 1. A brief description of the techniques, together with the quantitative data from a selection of completed bacteriological experiments and an account of the salient histological changes, will follow.

Female CBA mice were used; thymectomy was performed at the age of 6 weeks by the method of Taylor<sup>8</sup> and 2-4 weeks later the mice were given whole body irradiation, of either 600 r. or 900 r. Mice receiving 900 r. were immediately injected with bone marrow from female CBA mice, one donor supplying sufficient cells for three recipients.

Four separate suspensions of *Myco. leprae* were obtained by homogenizing skin biopsies from four unrelated

patients with active lepromatous leprosy. The methods of inoculating and collecting bacilli from foot pads and ears have already been described<sup>2,4</sup> and a similar method was used for collecting bacilli from the other tissues investigated.

Normal and T/r. animals, which had been injected with *Myco. leprae* into the four skin sites, were killed usually after 5 or 6 months and thereafter at 2 monthly intervals. Homogenates of each of the foot pads and ears were counted separately to obtain the total number of bacilli, and the number of non-viable organisms present, the number of viable organisms being determined by subtraction<sup>9</sup>. The animals injected intravenously were killed as follows: normal animals, 7, 10, 12, 16 and 22 months, and thymectomized and irradiated (with 900 r.) animals 6, 12, 14, 16 and 19 months, after inoculation.

Fig. 1 shows the counts obtained in the early stages after the injection of  $10^4$  *Myco. leprae* into each site in one of the four experiments. Thymectomy and 900 r. significantly enhanced the infection and multiplication was continued for 13 months with a slight fall off at 16 months, whereas multiplication fluctuated in untreated animals. Fig. 2 illustrates the effect of replacing the equivalent of total mouse lymphoid tissue immediately after thymectomy and irradiation with 900 r. and thereafter at 3 monthly intervals, in mice inoculated with  $10^4$  bacilli into the four skin sites. It shows that the severity of the infection was significantly reduced by this means but not to the level it assumed in normal animals.

In another experiment we showed that total body irradiation of 600 r. was less effective than a lethal dose of 900 r. This means that doses less than those necessitating bone marrow transfusions will not permit maximum yields of bacilli to be obtained in thymectomized mice.

Although inocula of  $10^6$  *Myco. leprae* failed to multiply in the four skin sites of normal mice, such inocula multiplied as freely in thymectomized animals irradiated with 900 r. as did inocula of  $10^4$  (Fig. 3). The count was still increasing after 16 months and it was in animals from this experiment that a systemic spread of the infection to the nose, forepaws, tail skin and leg muscles occurred

consistently 12 months after injection. In about half the animals in one experiment, swelling of the inoculated hind feet developed, and the skin covering the pad contained nodular swellings comparable with those in patients with lepromatous leprosy (Fig. 4). So far, no nodular swellings have affected the ears or sites of dissemination in animals from this experiment. Normal mice in this or any other experiment have never exhibited swellings.

In another experiment, mice were injected intravenously with  $3 \times 10^7$  *Myco. leprae* and the results show that a heavy systemic infection occurs only in the thymectomized animals irradiated with 900 r. (Table 2). The full significance of these findings is shown in Table 3, which shows that at 19 months, for example, 95 per cent of all the organisms recovered were in the nose, pinnae, fore and hind paws. Furthermore, the proportion of viable organisms from these sites was large, although not as great as from body and leg muscles. To test the significance of these observations more stringently, another thymectomized and irradiated mouse was killed at 19 months. The total yield of organisms from a homogenate of the whole animal was  $1.8 \times 10^{10}$  as against the summed total yield from its litter mate of  $9.8 \times 10^9$  (Table 3).

To test that the organisms from enhanced infections behave in the same way as *Myco. leprae* from patients, bacilli collected from different tissues in thymectomized and irradiated mice are being injected into the foot pads of normal mice. The behaviour of these organisms has

Fig. 3. Growth curves of *Myco. leprae* in skin sites of normal mice (A) injected with  $10^4$  bacilli and in thymectomized and irradiated mice injected with  $10^4$  (B) or  $10^5$  (C) bacilli. No growth was detected in normal mice injected with  $10^4$  bacilli. Each point represents the mean counts from both ears and both hind foot pads. ●—●, Total count; ×—×, "viable" count.

Fig. 4. Nodular swelling of hind foot pad in a thymectomized and irradiated mouse injected with  $10^4$  *Myco. leprae* 9 months earlier.

been bacteriologically indistinguishable from those derived from patients with lepromatous leprosy. To test further that the enhanced growth of bacilli in these mice was caused primarily by a reduction in immunity and not by any selection or change in the behaviour of the bacilli themselves, their growth was shown to be completely inhibited by feeding 0.01 per cent diaminodiphenyl sulphone, as it is in normal mice infected with bacilli from patients. There is thus substantial evidence that the

Table 3. LOCALIZATION AND YIELD OF *Myco. leprae* IN A THYMECTOMIZED AND IRRADIATED (900 r.) MOUSE 19 MONTHS AFTER INTRAVENOUS INJECTION OF  $3 \times 10^7$  BACILLI

Organ or tissue	Estimated bacillary yield		Degenerate bacilli (per cent)
	Per site ( $\times 10^6$ )	Per cent of total yield	
Hind foot pads	1,740	18	56

Total	9,755		

enhanced mycobacterial infection induced in these mice has the bacteriological characteristics of *Myco. leprae* as distinct from other mycobacteria.

The tissues were sub-divided so that they could be prepared for light, fluorescent and electron microscopy. Sections stained with haematoxylin and carbol fuchsin were scored for the number and viability of the organisms present in each unit volume of tissue before the actual number present on the contralateral side had been disclosed. There was complete agreement between these arbitrary scores and the actual number of organisms.

In the skin sites, the counts of which are recorded in Fig. 1, 5 months after injection there were scattered microcolonies of various sizes in voluntary muscle fibres in the normal foot pads<sup>7</sup>. The smaller colonies contained viable organisms, but some of the larger ones had ruptured and macrophages nearby contained non-viable organisms. By contrast, no non-viable organisms were found in the foot pads of thymectomized and irradiated animals and microcolonies in muscle fibres were more numerous, more widespread but smaller than in normal animals. There were a few viable organisms in macrophages and perineurial cells. No bacilli were seen in the skin of animals from either group. After 9 months there was no substantial change in foot pads from normal mice, but in the treated animals there were many more (2 plus) organisms. These bacilli were now more equally distributed in muscle fibres, in macrophages and in perineurial cells and most were still viable. Thirteen months after infection the number of organisms in the normal foot pads was about the same, but the proportion of non-viable forms had increased and were contained in both macrophages and in vacuoles in muscle fibres. In thymectomized animals irradiated with 900 r. the number of bacilli present had increased still further (3 plus) but a number of non-viable bacilli was found in macrophages and perineurial cells. Viable bacilli were seen for the first time among the sole plate nuclei of motor nerves and in neighbouring Schwann cells.

The histological situation in tissues from sites in which counts are recorded in Fig. 2 after lymphoid replacement was similar after 9 months in the three foot pads examined. There were numerous but very small microcolonies filled with closely packed viable organisms in voluntary muscle fibres. There was also a large number of empty bacillar cell walls in the cytoplasm of Schwann cells of motor nerve fibres, among sole plate nuclei in perineurial cells and a few in macrophages. The total number of organisms was scored as 1 plus.

Fig. 5. Electron micrograph showing globus and foam (Virchow) cell in forepaw dermis of a thymectomized and irradiated (900 r.) mouse injected intravenously with  $3 \times 10^7$  *Myco. leprae* 17.5 months earlier. G, Globus; F, foam cell.

From other experiments, four samples have been selected to demonstrate the histological changes in increasingly severe infections. (a) In a foot pad from a thymectomized and irradiated mouse which had been injected with  $10^4$  *Myco. leprae* 6 months previously, the infection was severe (3 plus). There were numerous microcolonies of viable bacilli in muscle fibres but almost as many in perineurial cells and macrophages. Microcolonies were no longer confined to perineurial cells around nerve bundles in muscles but had spread to similar cells in the dermis. Bacilli were also disseminating from perineurial cells to neighbouring cells which were clustered around neuromuscular bundles. There were also organisms in motor nerve Schwann cells and in pericytes surrounding blood capillaries. The number of non-viable organisms, particularly those in macrophages, had increased sharply. (b) The second sample was from one of the enlarged foot pads. The skin was several mm thick and sections from it, stained with haematoxylin and carbol fuchsin, were indistinguishable from those of skin covering nodules in patients with lepromatous leprosy. Its bacillary content was 6 plus. There were numerous globi in the dermis filled with viable bacilli as well as foam (Virchow) cells in all stages of development. There were viable organisms in the endothelial lining of capillaries, as well as in perineurial and Schwann cells of cutaneous nerves. The dermis which contained the majority of intracellular bacilli was separated from an unusually flattened epidermis by a zone containing very few cells (similar to the "clear zone" in the skin of patients with lepromatous leprosy). At intervals there were chains of bacilli passing across this zone from the dermis into and through the epidermis as far as the keratinized layer from which they were being shed. The bacilli lay in the cytoplasm of cells with long thin processes which connected nerve bundles in the dermis to the epidermis. The cytoplasm of the cells forming the terminal links of these chains also passed into the epidermis along with the bacilli. The medial plantar nerve was also very heavily infected with numerous globi in perineurial and Schwann cells, and there were also foam cells in all stages of development. (c) The third sample was cartilage from the nose of a thymectomized and irradiated animal injected intravenously with *Myco. leprae* 14 months previously. It was covered by a very heavily infected mucoperichondrium which was stuffed full of globi containing viable bacilli. Some of the globi had ruptured through the overlying mucous membrane. The bacilli which had left, and were still leaving them, had become embedded in mucus lying within and also lining the walls of the nasal cavity. (d) The fourth sample was the pad of a forepaw from a thymectomized and irradiated animal which had also been injected intravenously 17.5 months earlier. The skin was comparable in all respects with that from a patient with lepromatous leprosy. Fig. 5 is an electron micrograph showing a small globus containing viable organisms, together with a foam (Virchow) cell lying in the dermis of the skin of the forepaw.

Such infected animals are now being used as a model to analyse the disease process induced by *Myco. leprae* and the source and nature of the inflammatory cells involved.

One of us (A. G. M. W.) would like to thank the Nuffield, Rockefeller and Wellcome Trust Foundations, the Medical Research Council, the Ministry of Overseas Development and Leprosy for financial support.

## LETTERS TO THE EDITOR

## ASTRONOMY

## Radio Emission from the Sources 3C 225 and 3C 267

THE possibility of a relationship between radio galaxies and quasi-stellar sources is of great importance not only as a means for distinguishing between a local and cosmological theory of the latter sources, but also because if such a relationship does exist it would provide important evidence on the physical processes occurring<sup>1</sup>.

The term quasi-stellar sources as used by Schmidt<sup>2</sup> and E. M. Burbidge<sup>3</sup> refers to compact, blue, optical objects of stellar appearance with appreciable red-shifts; not all these objects are powerful sources of radio emission. Of those that are, some show a low frequency cut-off in their spectrum<sup>4</sup> or extremely small angular diameter<sup>5-9</sup>, but these features are by no means uniquely characteristic of this class of object. It is likely that intense optical and radio emission occurs for only a limited period and, because their lifetimes may be different, such characteristics may appear at different periods during the evolution of the same object.

Examples of blue stellar objects, associated with extensive radio sources without any compact radio component, are now known (for example, 3C 47), as well as extensive radio sources which contain a very compact radio component associated with a blue stellar object (for example, 3C 273).

Here we shall describe observations of two radio sources of large angular extent each containing a compact component without any apparent associated blue object despite the fact that the large angular extent implies a moderate distance. Unless the two components of each source represent a chance association, the observations

suggest that the intense optical emission has been of limited intensity or duration.

The observations were made with the one-mile radio telescope at Cambridge at frequencies of 408 and 1,407 Mc/s. The method of observation was the same as that already described<sup>10</sup>. The maps of the two sources are presented in co-ordinates in which the beam is circular; this involves the compression of the declination scale by a factor of about four in both cases.

3C 225. A map of the source obtained at 1,407 Mc/s is shown in Fig. 1. The source comprises two components separated by 374 sec arc in position angle (P.A.) 165°. Both are unresolved with upper limits to the angular diameters of 10 sec arc in right ascension and 40 sec arc in declination. The components are of unequal intensity, component B contributing about 70 per cent of the total emission. Positions, flux densities at both frequencies and derived spectral indices are given in Table 1.

Source	Right ascension	Declination	Flux density ( $\times 10^{-26}$ w/m <sup>2</sup> (c/s))		Spectral index
			1,407 Mc/s	408 Mc/s	
3C 225 A	09h 39m 25.3s	14° 05' 36"	1.50	3.4	0.65
	09 39 32.3	13 59 32	3.30	8.6	0.77
3C 267 A	11 47 20.8	13 04 00	1.77	7.2	0.73
	11 47 23.2	13 04 11	1.11		

There is good evidence for believing that a component of very small angular size exists. Observations with an interferometer of large baseline<sup>5,6</sup> at frequencies of 159 and 408 Mc/s have indicated a component having a diameter of less than 0.6 sec arc, and recent observations at 178 Mc/s by Little and Hewish<sup>9</sup> of the scintillation caused by the interplanetary medium have indicated that 30–40 per cent of the emission at this frequency must originate in a region less than 0.2 sec arc in extent.

The simplest interpretation is to identify the compact source with the weaker of the two components of Fig. 1. Support for this is provided by the 178 Mc/s observations, which were re-examined for us by Mr Little; they were made with a fan-beam transit instrument and show the maximum of scintillation  $4 \pm 2$  sec earlier than the maximum response—a figure which may be compared with the value 5.1 sec by which the weaker component occurs earlier than the centroid at this frequency.

The presence of such a compact source suggests that at low frequencies the effects of synchrotron self-absorption might be apparent. Williams<sup>4</sup> has shown that sources of diameter 0.2 sec arc and spectra as in Table 1 become optically thick at frequencies of about 50 Mc/s—a figure which is comparatively insensitive to the value of  $10^{-4}$  gauss assumed for the magnetic field. The total flux density at frequencies well below 50 Mc/s would therefore be entirely that from component B and would be about 30 per cent less than that expected by simple extrapolation from higher frequencies.

Observations of the total flux density of 3C 225 over a wide range of frequency<sup>11-17</sup> are plotted in Fig. 2; these include values given to us by Costain and Roger at 22.25 Mc/s and by Bridle at 10 Mc/s. It also shows as open circles the separate contributions from the two components derived from the present observations. It can be seen that the measured values are fully consistent with the adopted model in which the spectrum of component B is straight over the entire frequency range while that of component A has a cut-off at about 50 Mc/s.

A search for related optical objects on the *Sky Survey* prints shows no conclusive identifications, and certainly none as intense as might be expected for a source of such large angular extent. Using the model for extragalactic sources proposed recently<sup>1</sup>, the distance of 3C 225 is unlikely to exceed 500 Mparsec and an object as bright intrinsically as other quasi-stellar sources would have an m<sub>pg</sub> of about 13.

3C 267. The 1,407 Mc/s map of 3C 267 is shown in Fig. 3. The source consists of two components of unequal

Fig. 1. The map of 3C 225 at 1,407 Mc/s. The declination scale has been compressed by  $\sin \delta$ ; the beam is shown by the shaded circle. The optical objects marked are (a) 17.2<sup>m</sup> blue stellar object; (b) 18.0<sup>m</sup> red galaxy; (c) 19.0<sup>m</sup> slightly blue galaxy; (d) 19.5<sup>m</sup> red galaxy; (e) 14.0<sup>m</sup> slightly red stellar object; (f) 20<sup>m</sup> red object. D. Willis has provided a spectrum which shows it to be a star.

flux density separated by 37 sec arc in P.A.  $73^\circ$ . Positions and flux densities of the components are given in Table 1. Both components are unresolved, with upper limits to the angular size of 10 sec arc in right ascension and 40 sec arc in declination. Observations of the source by Cohen<sup>18</sup> at 430 Mc/s showed scintillation due to the interplanetary medium, suggesting that about 30 per cent of the radiation must originate in a region less than 0.2 sec

Fig. 2. The present observations of flux density ( $\circ$ ) for the two components can account for the observed spectrum if the weaker has angular size less than 0.2 sec arc and shows synchrotron self-absorption below about 50 Mc/s. This would also account for the observed degree of scintillation and the results of long baseline interferometry.  $\bullet$ , Total flux density.

Fig. 3. The map of 3C 267 at 1,407 Mc/s. The declination scale has been compressed by  $\sin \delta$ ; the beam is shown by the shaded circle. The cross marks a 20<sup>m</sup> red object.

Fig. 4. The spectrum of the total flux density of 3C 267 shows marked curvature similar to that in the total spectrum of 3C 225.

arc. The compact source is expected to show synchrotron self-absorption and the spectrum of the total flux density (Fig. 4)<sup>11-14</sup> shows a curvature at low frequency very similar to that of 3C 225.

An extremely faint red object at the limit of the 48 in. *Sky Survey* plates ( $\sim 20^m$ ) found by Véron<sup>19</sup> is marked with a cross. There are no other objects brighter than 20<sup>m</sup> within 30 sec arc of the components or the line joining them.

These sources, while being of very considerable total extent, nevertheless contain an extremely compact component which shows low frequency self-absorption. The absence of any blue object which can reasonably be associated with either radio source may imply a difference in lifetime of the optical and radio emitting regions.

We thank Drs C. H. Costain, R. S. Roger and P. J. S. Williams and Messrs A. H. Bridle and L. T. Little for permission to use unpublished material.

## Stonehenge 56 Year Cycle

Colton and Martin<sup>1</sup> are to be congratulated on the independent discovery of eclipse cycles based on a fixed number of lunations. The cycles that they list are among the long list of cycles which have been exhaustively studied and described in a rare book by Professor G. van den Bergh<sup>2</sup> that is seldom found outside astronomical libraries. The particular cycles tabulated by Colton and Martin are named, in order of increasing length, *Hepton*, *Octon*, *Inex*, etc.

Colton and Martin's conclusions, however, have no direct bearing on the Stonehenge eclipse cycle that I have proposed<sup>3</sup>. I did not, as they claim, attempt "to find an eclipse cycle which gives eclipses on the same calendar date". Indeed, I would hesitate to suggest that the inhabitants of Stonehenge recognized calendar dates based on a full solar year. In my opinion they were interested in eclipses during the midwinter and midsummer lunation, and possibly the lunations of the equinox. In contemporary usage it would be similar to asking when the "Harvest moon" or "Easter moon" will be eclipsed.

It is interesting to note in passing that the calendar-date cycle of 65 years, preferred by Colton and Martin, is one full Stonehenge cycle<sup>3</sup> of 56 years plus the next sub-interval of 9 years. Elsewhere I have presented graphic illustration of this solstice cycle<sup>4</sup> and some interesting implications of it are considered by various authors in the issue of *Antiquity* for June 1967.

### Is a Quasar Nucleus a Star Cluster or a Single Body?

It has been suggested<sup>1</sup> that the optical variability of the quasi-stellar source 3C 273 is compatible with a model of a quasar which is a complex of several sources of the same type; for example, a star cluster within which there are independent occasional collisions and possibly flash-like supernovae as well. This claim is incorrect. In fact, the statistical properties of the optical variability of 3C 273 are such as to suggest that the separate parts of a quasar nucleus interact with each other. In other words, a quasar nucleus is in the limit of a single body<sup>2</sup>.

The conflicting views that quasar radiation can<sup>1</sup> and cannot<sup>2</sup> be interpreted by the superposition of independent occasional events can be formulated from the point of view of mathematical statistics, respectively, as the hypotheses: (A) the one-dimensional distribution of the intensity of the quasar radiation  $x(t)$  is Gaussian; (B) the distribution  $x(t)$  differs significantly from the Gaussian form. It should be emphasized, first of all, that it is not possible to distinguish between the hypotheses A and B by the spectral density of the optical signal (the Fourier transform of an auto-correlation function), which is the assumption of ref. 1. This arises from a theorem, well known in the theory of noise<sup>3</sup>, that any spectral density is equivalent to an appropriate sequence of identical impulses occurring at independent instants of time. Moreover, sampling spectral density at low frequencies is not representative as a rule<sup>4</sup>. Indeed, the ratio of the standard deviation of the sampling spectral density to its mean value appears to be near to unity in the low frequency range ( $\sim 0.1 \text{ yr}^{-1}$ ) of the light variation of 3C 273, to which the authors of the work<sup>1</sup> attach determinant importance.

Direct verification of the validity of the Gaussian law for the one-dimensional distribution of the brightness record  $x(t)$  seems to be possible by making a constructive distinction between hypotheses A and B. For a quasi-periodical signal, it is more convenient from a practical point of view to consider its envelope  $R(t)$

$$x(t) = R(t) \cos [\omega t + \theta(t)]$$

where the envelope  $R(t)$  and the phase  $\theta(t)$  can always be chosen independently<sup>5,6</sup>. For the case in question such a choice can be realized as follows

$$R(t) = \sqrt{\left(x^2 + \frac{1}{\omega^2} \left(\frac{dx}{dt}\right)^2\right)}, \quad \omega^2 = (2\pi/T)^2$$

$\omega^2$  is taken to be  $0.5 \text{ years}^{-2}$  in accordance with  $T \simeq 9$  years (see ref. 2)\*.

\* In this case, direct calculations give  $r(R, \theta) \simeq 0.06$  for the sampling correlation coefficient, and  $\sigma_r \simeq 0.16$  for the standard deviation, which confirms the non-correlativity of  $R(t)$  and  $\theta(t)$ .

If hypothesis A was valid,  $R(t)$  would have the Rayleigh distribution<sup>6</sup>, the density of which is

$$f(R) = \frac{\pi}{2R_0^2} \exp(-\pi R^2/4R_0^2)$$

where  $R_0 = \varepsilon(R)$  is a mathematical expectation, and  $\sigma_R = R_0 (4/\pi - 1)^{1/2}$  is a standard deviation. The significance test can be made using the variability coefficient of the sampling envelope<sup>7</sup>  $v = s/\bar{R}$ , where  $s$  is a sampling standard deviation and  $\bar{R}$  is a sample mean. It is possible to show that for the Rayleigh distribution

$$\varepsilon_v = \left(\frac{4}{\pi} - 1\right)^{1/2} = 0.523$$

$$\sigma_v = 0.372 n^{-1/2} + O(n^{-3/2})$$

To refer to the same statistical data<sup>2</sup> on the light variability of 3C 273 that were used in ref. 1, there are seventy-one values of  $R$ , correlated (due to smoothing) within 2 years, that is,  $n = 35$  independent values, so that  $\sigma_v = 0.063$ . The Rayleigh distribution is rejected at the 1 per cent significance level, if

$$|v - \varepsilon_v| > 2.58 \sigma_v$$

if  $v < 0.36$  or  $v > 0.68$ . According to ref. 2,  $v = 0.34$ . Hence, the Rayleigh distribution of the brightness envelope of 3C 273, and consequently that of hypothesis A, is rejected with 99 per cent confidence, which is uncommonly high for astrophysical problems.

Thus the optical variability of the 3C 273 quasar cannot be interpreted as a result of the superposition of independent random flashes in a compact star cluster. On the other hand, is it possible that this model is valid for other quasars where there are not yet enough data available for the variability?

There are serious objections to any hypothesis of a quasar nucleus as a compact star cluster. Some of these are based on considerations of energy, as has already been pointed out elsewhere<sup>2,8</sup>. In addition, in a detailed model of stellar collisions<sup>9</sup> it was shown that for the necessary quasar radiation power the energy release for each supernova (which is considered to have resulted from stellar collisions) should be  $10^3$ – $10^4$  times the energy release of the supernova observed in the optical region. If this rigid demand, which is likely to be unreal, be rejected, then the initial number of stars  $N$  may be much larger. In this case the time of formation of a compact cluster, proportional to  $N^2$ , is sharply increased, and it is not clear how this difficulty can be eliminated while retaining an element of catastrophe as a necessary requirement for a quasar formation. In this model some other serious difficulties of a cosmogonic nature are also encountered<sup>10</sup>.

The unacceptability of the model of a compact star cluster as an energy source can be shown by a far-reaching analogy between quasars, on the one hand, and radio galaxies, Seyfert galaxies, and the nuclei of common galaxies on the other.

The fact that the radio variability of the nucleus of the Seyfert galaxy NGC 1275 is similar to that of quasars<sup>11</sup> leaves little doubt about the fact that the nature of the physical processes in these objects is the same, but differs in the scope of its activity. This is also indicated by the discovery of strong infra-red radiation from the nucleus of the Seyfert galaxy NGC 1068, the spectrum of which is similar to the infra-red spectrum of 3C 273 (ref. 12). Meanwhile, an attempt to interpret these phenomena in the framework of a model of a compact star cluster encounters great difficulties on energy grounds, the more so because the reliability of the distances to these objects, unlike those to quasars, can no longer be disputed. The insurmountable nature of these difficulties is particularly clear in the interpretation of the infra-red source in the nucleus of our galaxy, the size of which is less than 0.2 parsec and which has a complete power of more than  $10^{39}$  ergs/sec (ref. 13). In this case the

average density of stars appears to be more than  $10^8$  parsec $^{-3}$ , that is, such compact clusters cannot exist for long periods of time. Finally, a direct argument against the model of a star cluster is quasar 3C 446, in which a rapid variability is found, showing that the source sizes are less than  $3 \times 10^{14}$  cm (see ref. 14). It is quite inconceivable that stars could preserve their individuality in this situation.

Thus the idea of a quasar nucleus as a compact star cluster encounters great difficulties of an energetic and cosmogonic character and is in marked contrast with the observed optical variability of 3C 273. At the same time, the assumption that the radiation source of the quasar nucleus is, in the limiting case, a single body (that is, the whole complex of strongly interacting fields) finds its direct verification in the statistical analysis of light variation of 3C 273. A general theoretical study of a possible nature of this single body and the display of its properties in a variable radiation flux is given in refs. 8 and 10.

### Subtractive Dispersion Spectrographs of Possible Use in Ultra-violet Stellar Research

THE relative intensity of the short wavelengths in stellar spectra can be increased by means of a partial achromatization device consisting of two reflexion gratings. Experiments at this observatory have given promising results, and suggest that devices like this may have applications in space research as well as in conventional astronomy.

*Methods using a prism and a grating.* This principle has already been described by Wood<sup>1</sup> as a "partial achromatization by means of a grating", but it does not seem to have been used in ultra-violet stellar research. By subtracting the dispersion of a prism from that produced by a grating, a very low dispersion may be obtained in the ultra-violet even though the dispersion for longer wavelengths may still be considerable. In order to obtain a partial achromatization (spectrum turning in the far ultra-violet), however, the prism must have a large refracting angle. This may be a drawback of this method for space research, particularly if an objective prism is used. We have nevertheless made promising experiments in the laboratory indicating that such devices may be very useful for special purposes.

*Methods using two gratings or one grating combined with a plane mirror.* Wood<sup>2</sup> has described the use of two crossed gratings for removing ghosts. A similar arrangement has been used at the US Naval Research Laboratory

for avoiding stray light in a spectrograph<sup>3</sup>. The use of two consecutive concave gratings for producing an image of the Sun by means of a narrow part of its spectrum has also been considered before<sup>4</sup>, but I have not been able to find in the literature a report of the use of two consecutive plane gratings as a subtractive dispersion device for decreasing the dispersion in the violet. According to experiments made recently at the Swedish Solar Observatory in Anacapri, this method looks perhaps the most promising one for this purpose, and a few details may be of interest.

Let the angle of incidence for the two gratings be  $i_1$  and  $i_2$  and the angle of emergence  $\vartheta_1$  and  $\vartheta_2$ , and let the angle between the two gratings be  $\gamma$ . If the grating constant  $\sigma$  is the same for the two gratings and if the wavelength  $\lambda$  is observed in the first orders, the combined effect may be described by the well known grating formulae as follows

$$\begin{aligned}\sin \vartheta_1 &= \sin i_1 + \frac{\lambda}{\sigma} \\ i_2 &= \gamma - \vartheta_1 \\ \sin \vartheta_2 &= \sin i_2 + \frac{\lambda}{\sigma}\end{aligned}\quad (1)$$

By using suitable values of  $i_1$  and  $\gamma$ , partial achromatization may be achieved. The phenomenon is described by the function  $\vartheta_2(\lambda)$ . Fig. 1 gives three examples of this function calculated according to the equations (1) and with the assumption that the gratings have 576 grooves per mm and that the angle  $\gamma$  is  $40^\circ$ . The three curves correspond to angles of incidence  $i_1$  of  $5^\circ$ ,  $7^\circ$  and  $9^\circ$  respectively, giving angles of emergence  $\vartheta_2$  of  $36.6^\circ$ ,  $34.2^\circ$  and  $31.9^\circ$  for the three wavelengths of about 4500 Å, 3800 Å and 3000 Å corresponding to the vertices of the dispersion curves. This means that in all three cases the spectrum is returning, which produces an overlap of long and short wavelengths. This overlapping can be avoided, however, if the two gratings are rotated through a small angle in opposite directions. A most spectacular phenomenon is displayed if the slit of the spectrograph is divided into intervals (Fig. 2), so that the two branches are separated. The following relations give the vertex directions

$$\begin{aligned}\vartheta_1 &= i_2 = \frac{\gamma}{2} \\ \sin \vartheta_2 &= \sin \frac{\gamma}{2} + \frac{\lambda}{\sigma} = 2 \sin \frac{\gamma}{2} - \sin i_1\end{aligned}\quad (2)$$

Fig. 2 shows two subtractive dispersion spectra which I have obtained at Anacapri with the use of two Siegbahn gratings and with the Sun as source. The long wavelengths are seen in the longer branches of the two images with the

Fig. 1. Different dispersion curves for a combination of two plane gratings giving dispersions in opposite directions.

Fig. 2. Two solar spectra obtained by the use of two slightly inclined gratings and showing partial achromatization. The longer branches correspond to longer wavelengths, the shorter branches to shorter wavelengths.

H $\alpha$  line to the right. Despite the use of Eastman 'E IV' films, which have a low sensitivity in the green, the decrease in dispersion towards the vertex point produces a very uniform density on the film. The shorter branches show the violet and ultra-violet parts of the spectrum with the H and K lines slightly out of focus. In this branch the dispersion increases towards the shorter wavelengths, giving a rapid decrease in density with increasing distance from the vertex point. The phenomenon corresponds more or less to the curve valid for  $i_1 = 5^\circ$  in Fig. 1.

We have also carried out experiments with one grating combined with a plane mirror and have found effects similar to those with two gratings. It should be noted that diffraction gratings have previously been combined with plane mirrors<sup>5</sup>, not for the purpose of producing partial achromatization but for increasing resolving power. For our purpose, the use of two suitably blazed gratings seems to give greater intensity and less disturbing overlap. The gratings should have a good blaze in the first order and for the appropriate directions. In this way a very satisfactory intensity will be obtained, particularly at the vertex point, which may appear as a brilliant feature in the spectra.

The two grating device may be used in front of a telescope in the same way as an objective prism or in a spectrograph, with or without a slit. When used as an objective grating, the fairly rapid change in the spectrum with varying angle of incidence  $i_1$  may introduce some limitations. As may be inferred from Fig. 1, a change in  $i_1$  of one degree produces a change in the vertex position of slightly more than twice this amount. To some extent, photometric corrections for this effect seem possible, however. As far as can be judged from laboratory experiments, colorimetric work would seem possible, particularly by using the brilliant region at the vertex point. This may allow photometric measurements of the continuous spectrum far out in the ultra-violet. For somewhat longer wavelengths, real spectrophotometry will be possible.

By using two slightly inclined gratings (Fig. 2) and selecting a vertex point at about 4500 Å or so, the two branches of the spectrum of a nebula or similar object showing large Doppler shifts may be compared in order to determine radial velocities in spectra obtained without slit. If this is feasible, the method would have some traces in common with Fehrenbach's<sup>6</sup> method of measuring two reversed spectra obtained with two independent prisms.

Finally, the device may also have applications in solar physics. The brilliant vertex point may make it possible to obtain, for example, prominences at the limb in selected spectrum regions. When studying the prominences (or the disk) in the Balmer continuum or other continua, such a broad-band filter may be of value even if the solar image is elongated and not circular.

## PLANETARY SCIENCE

### Lunar Variations in Auroral Zone

AN investigation of the frequency content of the geomagnetic record, collected during the IGY/IGC at several stations spread over the globe, has been carried out by high resolution spectrum analysis. I have already described the method<sup>1</sup> and a detailed discussion of the analysis will appear elsewhere. At most of the stations, besides the solar harmonics, several lunar tidal lines and luni-solar lines appeared significantly above the noise level of the spectrum. The amplitudes of these lines have been estimated from the power energy of the appropriate peak in the spectrum; in this note only the variation of the amplitude of the harmonic terms  $L_1$ ,  $L_2$  and  $L_3$  with respect to the dipole latitude is considered. The frequencies of these lines as calculated by Chapman's formula are 0.93227, 1.93227 and 2.93227 cycles per day respectively and the frequencies of the corresponding lunar tide lines  $O_1$ ,  $M_2$  and  $M'_3$  (corresponding to the term  $A_{84}$  of Schureman<sup>2</sup>) are respectively 0.92953, 1.93227 and 2.93427 cycles per day. With the frequency interval (0.00416666 cycles per day) allowed for in the spectrum analysis, the minor differences in the frequencies of the luni-solar and the tidal lines remain indistinguishable and the resultant effect appears as a peak in the spectrum.

Simple tidal theory indicates that the diurnal and semi-diurnal terms of the lunar tide vary with latitude  $\lambda$  as  $\sin 2\lambda$  and  $\cos^2\lambda$  respectively<sup>3</sup>. The important thing to notice is that because  $\cos^2\lambda$  approaches zero faster than  $\sin 2\lambda$ , at higher latitudes ( $> 45^\circ$ ) the dominance of the semi-diurnal tide decreases and the diurnal term becomes discernible. In the auroral zone, for example, near a latitude of  $65^\circ$ , the values of  $\sin 2\lambda$  and  $\cos^2\lambda$  are respectively 0.77 and 0.18 and thus the diurnal term has a favourably high coefficient in the auroral zone—a region of high conductivity in the overhead ionosphere because of the large charged particle precipitation.

A study of Fig. 1 indicates that the amplitudes of the resultant harmonic terms are considerably larger in the equatorial and in the auroral zones. It has been suggested by Matsushita<sup>4,5</sup> that the large amplitude of the lunar geomagnetic variation in the equatorial zone is due to a lunar equatorial electrojet. On either side of this equatorial electrojet belt the amplitudes of the lines ( $L_1$ ,  $L_2$ ,  $L_3$ ) as seen in Fig. 1 are small, but there is a sudden and considerable increase in their amplitudes within the auroral zone in either hemisphere, the amplitude of the line  $L_1$  being maximum. Beyond the auroral zone the amplitudes of these lines are smaller but still larger than those in mid and low latitudes and the diurnal effect predominates.

Fig. 1. Variation of the amplitude of the lines  $L_1$ ,  $L_2$  and  $L_3$  with the geomagnetic dipole latitude.

In the auroral zone, the diurnal tidal effect aided by the enormously large diurnal variation of conductivity due to particle precipitation seems to give rise to a lunar auroral electrojet which seems responsible for the large amplitudes of the lines  $L_1$ ,  $L_2$ ,  $L_3$ . Also, the phase differences computed in the cross spectrum analysis between the data from different stations, lying in the auroral zone, possess the same sign at luni-solar harmonics as at the solar harmonics. This indicates that the current system responsible for these large luni-solar variations in the auroral zone flows in the same direction as the well known auroral electrojet. Further studies of this luni-solar effect through geomagnetic and ionospheric record, taken in the auroral zone, are required to verify this conclusion.

I thank Professor Gordon J. F. MacDonald for assistance during this work.

### Faunal Evidence bearing on the Age of Late Cambrian - Early Ordovician Metamorphism in Britain and Norway

It can no longer be stated categorically that metamorphism of the Dalradian Series in Connemara occurred before the *Didymograptus extensus* zone of the Arenig Series, because those sediments generally accepted as the

earliest post-tectonic sediments in the area have provided a *Didymograptus bifidus* zone (Lower Llanvirn) graptolite fauna. This means that the only stratigraphical younger age limit which can be placed on the Dalradian metamorphism in Connemara is some time plane at or near the base of the *bifidus* zone. This upward extension of the younger, minimum stratigraphical limit of the Dalradian metamorphism necessarily extends considerably that interval in Late Cambrian-Early Ordovician times during which an important phase of orogeny could have taken place. Furthermore, the statement by Leggo *et al.*<sup>1</sup> that "the base of the Arenig would seem to be younger than  $510 \pm 35$  m.y.", on the evidence of the rubidium/strontium age given by the post-metamorphic and (hitherto) pre-Arenig Oughterard granite, should be amended to refer to the base of the *bifidus* zone.

In Connemara, the slates and cherts in the Sruffaunduff, south-west of the summit of Bencraff, Co. Galway, have long been regarded as the oldest sediments of the Ordovician succession in that part of Ireland<sup>2-4</sup> and they have yielded the graptolites which have been used to give the younger age limit to the main metamorphism of the Dalradian Connemara Schists. Carruthers and Muff<sup>2</sup> attributed the Bencraff fauna to the *extensus* zone, and Theokritoff<sup>3</sup>, in his review of the Ordovician rocks near Leenane, did likewise. The fauna listed from this locality is more suggestive of the *bifidus* zone, however, and this age has been confirmed by recently collected material. The following forms have been identified:

*Dichograptid* stipe fragments, gen. et sp(p). indet.  
*Didymograptus* cf. *dubitalis* Harris and Thomas  
? *Tetragraptus* sp. indet.  
*Tylograptus geniculiformis* Mu  
*Tylograptus geniculiformis* var. *flexilis* Mu  
*Glossograptus acanthus* Elles and Wood  
*Hallograptus inutilis* (Hall)  
*Glyptograptus austrodentatus* Harris and Keble subsp. indet.  
*Pseudoclimacograptus* cf. *angulatus angulatus* (Bulman)  
? *Amplexograptus* sp. indet.

Reference to the *bifidus* zone is indicated particularly by the presence of *Tylograptus geniculiformis* and also by the rich and varied biserial element in the fauna. The absence of pendent species of *Didymograptus*, so distinctive a feature of the *bifidus* zone elsewhere in Britain, is not significant in this case because the affinities of the Bencraff graptolites are clearly with the Pacific region (Australia, China and western North America) where such forms are rare or absent.

Elsewhere<sup>5</sup>, it has been suggested that the graptolite fauna described by Blake<sup>6</sup> from the Bogo Shale of the Trondheim region probably belongs in the *Didymograptus hirundo* zone of the standard British Ordovician graptolite zonal sequence. The graptolites are important in giving a younger age limit to the Trondheim orogenic phase because the Bogo Shale lines near the base of the post-orogenic Hovin Group, though its exact position relative to the basal conglomerate (Stokkvola = Vella = Fjeldheim) of the group is uncertain<sup>6,7</sup>. An older age limit for the movements is provided by the occurrence of *Dictyonema flabelliforme*, indicative of the lower part of the Tremadoc Series, in the pre-orogenic Røros Group of the Trondheim region<sup>8</sup>. Moreover, there are indications that the movements were concentrated later rather than earlier in the interval between the occurrence of *D. flabelliforme* and the *hirundo* zone graptolite fauna in the Bogo Shale. First, the pre-orogenic Støren Group is stratigraphically intermediate between the Røros and Hovin Groups, so that the movements were not only post-Røros Group but also post-Støren Group. Second, in the Digermul Peninsula, in Finnmark, there is an apparently unbroken succession of 3,000 m of completely conformable clastic sediments, extending from the Eocambrian through the Cambrian to the Tremadoc<sup>9</sup>, which terminates against an over-thrust metamorphic complex; this situation implies the absence of a major orogenic event in the Lower Palaeozoic of Northern Norway at

least until late Tremadocian times. This movement phase in Northern Norway has been equated with the Trondheim orogeny in the Trondheim region of Central Norway by Sturt *et al.*<sup>10</sup>.

It is not unlikely that the Trondheim movements were still operative as late as early *hirundo* zone times because some elements of the Bogo Shale fauna are suggestive of a position high in the *hirundo* zone and such an upper stratigraphical age limit for the Trondheim movements is only slightly earlier than that for the Dalradian metamorphism in Connemara. Moreover, Sturt *et al.*<sup>10</sup> have suggested that a principal phase of the Caledonian orogeny occurred at or before  $490 \times 10^6$  yr in Northern Norway. This is based on the potassium/argon ages given by a group of alkaline rocks which were emplaced at a late stage in the deformation-intrusion-metamorphism sequence. Such an age of orogeny agrees well with the postulated radiometric age of the Dalradian metamorphism in Connemara.

### Complete Late Pre-Cambrian to Early Palaeozoic Orogenic Cycle in Ghana, Togo and Dahomey

ISOTOPIC age determinations indicate the existence of a widespread  $500 \times 10^6$  yr thermal and metamorphic event, the "Pan African orogeny", which has affected most of the African shield outside three cratonic areas<sup>1</sup>. Black<sup>2</sup> has discussed the effects of this event on the West African craton and has concluded that it has the status of an orogeny. He drew attention to the way late Pre-Cambrian sediments lie partly on the craton and partly on the areas involved in the orogeny where they have been folded and metamorphosed.

I have distinguished sedimentary, structural and magmatic features in Ghana, Togo and Dahomey, which show that a complete orogenic cycle occurred in the late Pre-Cambrian and early Palaeozoic. Because in some parts of Africa the "Pan African orogeny" has been considered only as a thermal and metamorphic event, the recognition of a complete cycle in West Africa is of importance.

The understanding of the relationships within the sediments associated with the orogeny depends partly on abandoning the long-standing acceptance of uninformable relations between the Voltaian group and the Buem and Togo formations, and on recognizing that there is a measure of lateral equivalence between them.

The publications of the Ghana Geological Survey present a wealth of evidence supporting this view, of which I intend to present a detailed account elsewhere. For example, it has long been recognized that some sedimentary divisions—notably the Afram shales—lie in both the Buem formation and the Voltaian Group<sup>3-8</sup>.

Late Pre-Cambrian sedimentation began with the deposition of a series of fluvial and shallow water arenaceous sediments constituting the Lower Voltaian sandstones and the Togo quartzites. After this the orogenic cycle proper began and the tectonic differences between the stable craton and the mobile orogen started to influence the nature of the subsequent sedimentation. The overlying and laterally equivalent Voltaian Oti beds, Afram shales and Buem formation range from stable shelf or miogeosynclinal marine sediments, to sediments possessing eugeosynclinal characteristics. The Oti beds on the craton have a typical mudstone-shale-limestone association, with some of the limestones containing *Collenia*-like remains and sponge spicules. The Buem, on the other hand, includes greywackes, cherts, jaspers, a slide conglomerate, graded-bedding, slump-structures, and spilitic and pillow lavas<sup>9,11</sup>, and has clearly accumulated in a tectonically unstable environment. It is taken to represent a flysch deposit.

After the deposition of these sediments, orogenic folding affected the Buem and Togo formations and the uplift of this fold-belt constituted a source from which the molasse Obosum beds and Upper Voltaian sandstones were derived and deposited on the craton to the west. Palaeo-currents and grain-size variations in the Obosum beds clearly show their easterly source, and the intercalated conglomerates have a much higher proportion of plutonic rock fragments as compared with the earlier pre-orogenic Akroso conglomerate<sup>5</sup>.

The orogenic folding of the Buem and the Togo formations was accompanied by important thrust movements towards the west. Thrusts and mylonites often mark the contact between the Togo formation and the underlying crystalline Dahomeyan, and there are reasons for regarding the Buem and the Togo as tectonic units, frequently bounded by thrusts, and characterized by distinct sedimentary facies, tectonic style and metamorphic grade. Recent earthquake epicentres and posthumous fault movements mark the position of the orogenic belt at the present day<sup>8</sup>.

The associated igneous rocks range from the pre-orogenic Buem lavas which include both pillow and spilitic varieties, serpentinites and other ultra-basic rocks emplaced along thrust planes (refs. 12-14 and personal communication from K. C. A. Burke), and concordant and discordant granites. The granites are most abundant in the underlying crystalline Dahomeyan but also cut the Togo formation<sup>15</sup>. This igneous activity constitutes a normal orogenic igneous cycle.

The age of the sediments of the orogenic cycle is not precisely known, because no diagnostic fossils have been recorded from them. The small Accraian and Sekondian basins on the coast, which are likely to belong to the same sedimentary episode as the highest Voltaian, have yielded Devonian and Lower Carboniferous fossils. The recognition in better documented orogenic belts elsewhere that mineral isotopic ages may represent the time of the uplift of the belt and the onset of molasse sedimentation<sup>16,17</sup>, and not the time of the first crystallization, suggests that dates from the Dahomeyan<sup>18</sup> indicate that the deposition of the molasse Obosum beds began in the Upper Cambrian or the Lower Ordovician.

The existence of a complete late Pre-Cambrian to early Palaeozoic orogenic cycle in Ghana, Togo and Dahomey is of some importance to the hypothesis of continental drift. The recently reported discovery of  $2,000 \times 10^6$  yr and  $500 \times 10^6$  yr age provinces in the basement rocks of northern Brazil—which match the similar age provinces in West Africa when South America and Africa are fitted

together<sup>18</sup>—indicates that a similar complete orogenic cycle may also be present in northern Brazil.

I thank Professor Kevin Burke for his advice.

## New Zealand Region Volcanism and Structure

DURING 1959–65, five major New Zealand Oceanographic Institute cruises were completed, under the NZ Antarctic programme, in the subantarctic region south of New Zealand. Bathymetric data from these and other cruises dating back to 1950 have made it possible to define the morphology with reasonable accuracy over a 500,000 square mile area, between latitudes 48° and 57° S. and longitudes 157° and 180° E., the chief elements of which are Macquarie Ridge and the Campbell Plateau (Fig. 1). Fifty-two bedrock samples obtained on New Zealand Oceanographic Institute cruises add substantially to the previously limited geological data from this region, earlier obtainable only from the subantarctic islands sited on the ridge and plateau.

Until now, detailed analyses of the geology and structure of this region have not been possible because of the marked paucity of data. Seismic refraction studies show that Campbell Plateau is a section of continental crust with intermediate thickness<sup>1</sup>. Brodie<sup>2</sup> related the plateau to the Lord Howe Rise, suggesting that they might be formerly continuous structures dislocated by the Alpine Fault. Otherwise no attempt has been made to investigate the structure of the plateau.

From the seismicity of the Macquarie Ridge<sup>3,4</sup>, Ewing and Heezen<sup>5</sup> suggested that it was probably a branch of the mid-ocean ridge system. Continuity of the ridge from the New Zealand continental shelf to latitude 60° S. has been but recently demonstrated by Brodie and Dawson<sup>6</sup>. Hatherton has since implied that the ridge continues into southernmost New Zealand, where it is manifest as the isostatically undercompensated, upstanding Fiordland massif<sup>7</sup>.

Magnetic evidence from the South-western Pacific Basin south of the Campbell Plateau<sup>8</sup> demonstrates the existence of linear magnetic anomalies parallel both to the East Pacific Rise and the Antipodes Fracture Zone<sup>9</sup> forming the eastern margin of the Campbell Plateau.

All available data, including those most recently obtained by the New Zealand Oceanographic Institute, have been considered in an attempt to clarify the geology of structures on the sea floor south of New Zealand<sup>10</sup>. The narrow, arcuate, seismically active Macquarie Ridge, separated on its convex side from the Tasman Basin by a deep, narrow,

discontinuous trench, is most probably an island arc. Petrographic and chemical analyses of ridge basalts show them to be dominantly tholeiitic and similar in composition to Japanese tholeiitic basalts and dissimilar from mid-ocean ridge basalts. Between the ridge and the plateau is the seismically active Solander Trough in which Quaternary hornblende-andesites occur at Solander Island. The trough is part of a dilatational rift system comprising the Waiu Depression in the South Island, New Zealand, and the Emerald Basin, probably a newly formed ocean basin (Fig. 1). East of this rift occur the late Tertiary alkaline volcanics of the Auckland Islands<sup>11</sup>, Campbell Island, Dunedin<sup>12</sup>, and Banks Peninsula<sup>13</sup>. Such lateral transitions in magma type are typical of the transition zone between oceanic and continental crust in the circum-Pacific belt<sup>14</sup>. Here then is a continental margin similar to that recognized elsewhere in the circum-Pacific belt, fringing the Campbell Plateau for at least 500 km south of New Zealand. Recent geophysical investigations<sup>15</sup> show that earthquake foci increase in depth eastward away from Fiordland. This parallels the observed increase in alkalinity and once again is a feature typical of the circum-Pacific belt<sup>14</sup>. It supports the contention that the Macquarie–Solander island arc complex continues into southernmost New Zealand. The complex may have begun its development during the Oligocene, the age of oldest dated sediments in the Waiu Depression.

On the Campbell Plateau, the sparse geological data suggest Cretaceous planation followed by sinking of the plateau to about its present level<sup>16</sup>. Our recent data show tectonic development of broad east–west trending rises on the plateau (Fig. 1) culminating in late Tertiary volcanism. Some large-scale, simple geological process may relate the development of these Tertiary structures to the

Fig. 1. The New Zealand Region. Southern trenches > 5,000 m deep and Kermadec Trench > 6,000 m deep, black. Land, light stipple; terrestrial and continental shelf extensions of offshore rift depressions, heavy stipple; Antipodes Fracture Zone, heavy dashed line; axes of uplift on Campbell Plateau, double dashed line; A.I., Auckland Islands; C.I., Campbell Island. Bathymetry from *Bathymetry of the New Zealand Region*, N.Z. Oceanogr. Inst. Chart., Misc. Ser. (in the press). Mercator projection; depths in metres.

Tertiary Macquarie-Solander complex, of markedly different trend and character.

The linear magnetic anomalies on the floor of the South-western Pacific Basin south of the Campbell Plateau<sup>8</sup> probably indicate movement of the crust away from the crest of the East Pacific Rise in the manner proposed elsewhere by Vine and Matthews<sup>17</sup>. Abrupt termination of the Chatham Rise by the Antipodes Fracture Zone suggests the rise structures were formerly continuous beyond the fault. Similarly curtailed structures are to be found in West Antarctica, and the Antipodes Fracture Zone thus corresponds to a rift margin fracture caused by movement of New Zealand away from West Antarctica consequent on Tertiary development of the East Pacific Rise. Menard<sup>18</sup> has suggested that the East Pacific Rise commenced its evolution in the North Pacific and spread southward. Because island arc development may be related to crustal movements centred on mid-ocean rises<sup>18,19</sup>, Macquarie Ridge could have formed in response to this southward spread. Continued southward and westward development of the East Pacific Rise now appears to have disrupted the Macquarie Ridge, of which a former southern continuation may be found in the ridge on which the Balleny Islands are sited.

In the North Island of New Zealand, continental margin associations typical of the circum-Pacific belt are found; in the Tertiary-Quaternary volcanic zones alkalinity increases westward from the Hikurangi Trench<sup>20</sup> as also do maximum depths of earthquake foci<sup>21</sup>. Northwards the volcanically active Taupo Graben is continuous offshore in the Havre Trough<sup>22</sup>; Tonga-Kermadec Ridge is continuous onshore in the East Coast Ranges of the North Island; Tonga-Kermadec Trench continues south as Hikurangi Trench (Fig. 1). Thus the North Island, New Zealand, is the southern extremity of an active island arc complex. Its structure and volcanism mirror that of southernmost New Zealand which is the northern extremity of the active Macquarie Arc. Fiordland and the East Coast Ranges, on continental crust, are non-volcanic in contrast to their offshore prolongations the Macquarie and Kermadec Ridges. Separation of the ends of oppositely directed island arcs by the Alpine Fault (Fig. 1) suggests that this is a transform fault of the type defined by Wilson<sup>23</sup>. The disposition and development of the Tonga-Kermadec arc have already been explained in terms of interaction between crustal movement systems centred on the East Pacific Rise and the Indian Ocean branch of the mid-ocean ridge system<sup>19,24</sup>. Macquarie Ridge may initially have been similarly sited along a line of convergence between oppositely directed forces centred on the Indian Ocean and Pacific mid-ocean ridge systems. This system today is evidently at a different stage of development from that governing the volcanically active Kermadec-Tonga system to the north.

## Trend Surface Mapping of Raised Shorelines

THERE have been several attempts in recent months to illustrate and define the degree of tilting or deformation of the various raised shorelines in Scotland<sup>1</sup>. Considerable use has been made of shoreline distance diagrams or graphs, whereby heights of the raised beaches in a particular area are projected on to a baseline, usually drawn in the supposed direction of maximum tilt of the series of shorelines as a whole. Each separate raised beach height is shown as a point on the diagram, the position of which is defined by altitude (usually given above *O.D.*) and projected distance along the baseline: the shorelines are depicted by lines or zones on the diagram, which in some cases are calculated best-fit regression lines to the series of points representing a given shoreline; in other cases they have been fitted by eye.

In the sense that such diagrams are two-dimensional representations of height data which have areal distribution, they provide a partial picture and allow only limited analysis. A three-dimensional view may be obtained by fitting a simple plane to the data for each shoreline as has been done in the case of the main post-glacial shoreline in part of western Scotland<sup>2</sup>. More sophisticated analysis is possible, however, if higher order surfaces are considered. Techniques and applications of trend-surface mapping have been considered by Chorley and Haggett<sup>3</sup>, and the surface fitting programme described by Whitten<sup>4</sup> offers a convenient tool in the present context. As will be illustrated later, trend surface mapping provides a most useful method of presenting and analysing height data relating to raised shorelines. Regional trends may be precisely defined and an isobase map readily constructed. Local anomalies are revealed which raise further questions concerning the nature and causes of the deformation of the shorelines, and which in some cases may raise doubts as to whether the original assumption, that one is dealing with the same shoreline throughout, is correct.

Best-fit trend surfaces of linear, quadratic and cubic form have been fitted to the data recorded by McCann<sup>2</sup> for the main post-glacial shoreline in western Scotland, between the Firth of Lorne and Loch Broom, by the electronic computer programme described by Whitten<sup>4</sup>, using an 'IBM 7090' computer. The best-fit linear surface which had been fitted to the data previously, without the use of a computer, explains 60.27 per cent of the observed variation in height; the best-fit quadratic surface raises the level of "explanation" to 76.97 per cent, and the best-fit cubic surface to 78.23 per cent. In view of the small increase in "explanation" provided by the cubic as compared with the quadratic surface, the latter is considered most appropriate for further analysis.

This best-fit quadratic surface (Fig. 1) indicates that the simple trend of decreasing elevation of the shoreline in a north-westerly direction, illustrated by the linear surface<sup>2</sup>, is complicated by a zone of relatively high elevations in Skye, revealed in particular by the 21 ft. contour for the surface. The pattern of uniform decrease in elevation westwards and north-westwards, shown by the 45-25 ft. contours for the surface, holds true only for the south-western part of the area shown on the map. It may be suggested that the presence of the post-glacial shoreline in Skye at elevations somewhat greater than might be expected from considerations of the overall

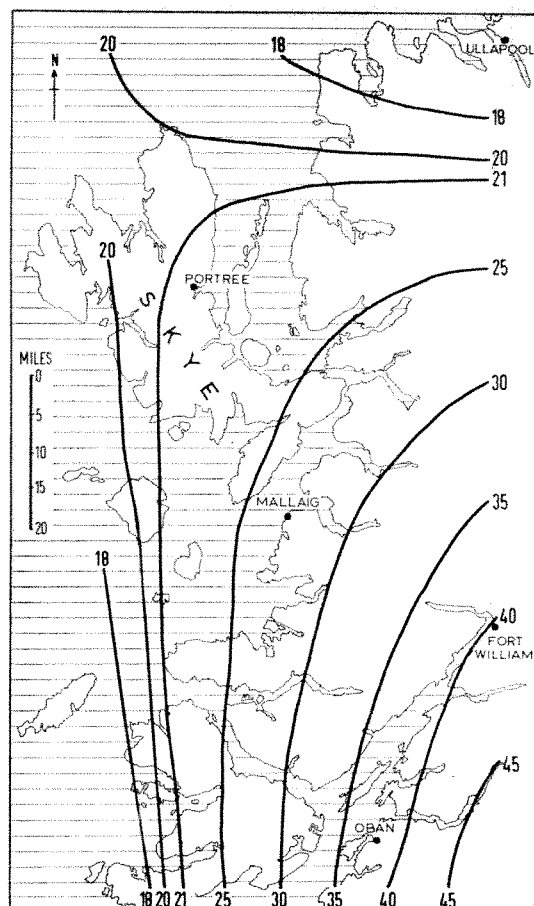

Fig. 1. Best-fit quadratic surface fitted to height data for the main post-glacial shoreline in western Scotland, between the Firth of Lorne and Loch Broom. Figures are given in feet above O.D.

pattern of deformation is a result of the greater isotatic depression of the land surface in that area due to the presence, at various stages in the glacial period, of a local Cuillins icecap. The trend surface offers no indication that one is dealing with more than one shoreline, and the map of the residuals from the surface, which may on occasion

provide additional information, appears to show little of significance in this case.

### Intercontinental Correlation of Late Pleistocene Sea Levels

EUSTATIC variations in sea level are assumed to be world wide and simultaneous. During the Pleistocene, sea level fluctuated in response to the formation and melting of continental glaciers, and interglacial shorelines higher than the present sea level are found in several places. Coastal areas which have been stable since the development of the Pleistocene shorelines have shoreline features at similar elevations. Conversely, the establishment of shorelines at similar elevations in different areas implies stability. Because of the effects of sedimentation, erosion, water loading and tectonic adjustment, no coast is completely stable. The effects of water loading<sup>2</sup> on the elevation of the interglacial shorelines (and modern) along a particular coast, however, are usually similar so that the relative elevations are not seriously disturbed.

This investigation compares the late Pleistocene shorelines of coastal Georgia<sup>3-7</sup> with those of southern South West Africa<sup>8,9</sup>. The late Pleistocene shorelines of Georgia have elevations of approximately 7.5 m (Pamlico), 4 m (Princess Anne), and 1.4 m (Silver Bluff) (Fig. 1). I shall not consider the older, higher Pleistocene shorelines which are present. The Pleistocene shorelines are approximately parallel to the coast and are horizontal within the accuracies of present techniques of measurement. Along these shorelines are sedimentary accumulations characteristic of barrier islands and lagoons; the maximum elevation of the barrier islands above sea level is thought to have been about 10 m. Lagoonal salt marsh becomes filled in to the approximate level of the former high tide. Assuming a Pleistocene tidal range similar to the modern range, the high tide level would be approximately 1.1 m

Fig. 1. Cross-section of central Georgia coast showing relation of Pleistocene and Holocene barrier island and lagoonal sediments to the Pamlico (7.5 m), Princess Anne (4 m), Silver Bluff (1.4 m) and Holocene shorelines. S.L. = Sea level.

above mean sea level. Despite erosion, compaction, and, in some areas, deposition, it is still possible to obtain a reasonable estimation of the former sea level.

A more precise method of estimating the mean sea level is based on the fossil burrows of the marine decapod *Callianassa* (*Ophiomorpha nodosa* Lungren)<sup>10</sup>. The modern form, *Callianassa major* Say, lives in the littoral and shallow neritic zones along the coast of the south-eastern United States. The animal is about 10 cm long and 1.2 cm in diameter and it constructs burrows in the soft sand usually 1.2–2 m long and about 1.6 cm in diameter except for the upper 20–25 cm which is constricted and not occupied by the animal. The principal burrow is approximately vertical; however, branches and bifurcations are common. It is maintained in the soft sand by a cementing agent produced by the animal. The cement penetrates the sand for a distance of 8–12 mm and it is the exterior of the cemented wall that is characteristic of the fossil burrow. Typically this external surface is covered with knobs 2–4 mm in height and 4–12 mm in diameter; however, the appearance of the knobs varies considerably depending on the permeability of the sand and other factors. Fossil burrows are known from Lower Cretaceous to present.

Modern *Callianassa major* lives in the beach as high as mean sea level. Using this criterion the elevations of the late Pleistocene seas have been determined at several places along 200 km of Georgia coast. Measurements for the Pamlico shoreline are 7 m, Princess Anne 3.7 m, and Silver Bluff 1.1 m (to these heights has been added an arbitrary 30 cm to compensate for erosion and the missing narrow part of the burrow). Thus it seems that if there has been movement it has affected the area as a whole.

Investigations along the coast of South West Africa cover an area from the Orange River north for a distance of about 100 km. During late Pleistocene time wave erosion produced sea cliffs as high as 3 m which were notched in places, and which had terraced surfaces seaward cut by deep gullies or surge channels. Zeuner<sup>11</sup> and Price<sup>12</sup> believe that the inner edge of such terraces represents sea level at the time of formation. On the coast of South West Africa there are four well-developed terraces complete with surge channels and sea cliffs. Despite minor irregularities, the three lower terraces are essentially horizontal along the coast. The fourth terrace, which is higher topographically as well as older than the other three, is warped from an elevation of about 40 m

near the Orange River to 8 m 100 km to the north-west.

The oldest of the three lower terraces has an elevation of about 8 m along the inner edge, the middle terrace an elevation of about 5 m, and the lower terrace an elevation of approximately 2 m (Fig. 2). These elevations are related to high stands of the sea at approximately these same levels. Deposits of marine sands and gravels overlie the terrace surfaces; in some cases where the cliff is low the gravels also overlap the cliff. The marine deposits overlying a terrace apparently result from a late phase of activity before the lowering of sea level which accompanied glacier formation and the succeeding submergences cut terraces at successively lower levels. The lowering of sea level after the formation of each terrace was sufficient to allow the development of stream channels in the terrace surface to below sea level<sup>9</sup>. This observation indicates fluctuations of sea level during the late Pleistocene rather than simply formation of successively lower terraces during stable periods in a general emergence.

The marine sands and gravels overlying the terraces are overlain by terrestrial sheet wash and aeolian deposits. The development of the Pleistocene shorelines might well have remained relatively unknown if it were not for the exceptional abundance of diamonds in the marine gravels overlying the terraces, which has made the complete removal of all sedimentary materials along these former shorelines economically feasible.

In spite of the contrast in mode of formation of the African and Georgian coasts, the elevations of the shorelines are essentially similar. The similarities of sequence and elevation suggest a general stability of the two areas during and since the development of these shorelines. The small differences in elevation can be explained in one or all of several ways. Regional tectonic movement in either or both areas may have resulted in slight elevation of the African area and/or a slight depression of the American area. The method establishing the mean sea levels may be slightly in error, because the inner edge of the eroded terrace and the base of the notched sea cliff may have formed, in this African area, 0.3–0.5 m above mean sea level. Also, hydrodynamic, meteorological, rotational or gravitational forces may have altered the shape of the hydrosphere and produced a slight variation in mean sea level during the late Pleistocene compared with the present time.

Uranium series dating of corals from the Key Largo limestone of southern Florida and the Bahama Islands

Fig. 2. Cross-section of coastal South West Africa 60 km north of the Orange River showing sea cliffs, terraces and beach deposits associated with the 8 m, 5 m and 2 m shorelines (after Stocken<sup>9</sup>). S.L. = Sea level.

suggest that the shorelines are late Pleistocene in age. The dates range from 100,000 to 170,000 yr B.P. and are thought to correspond to a high stand of the sea during the Sangamon (Riss-Würm) interglacial stages<sup>13</sup>. The Kay Largo limestone is correlated with the Pamlico (7.5 m) shoreline. Several radiocarbon dates of shells from Silver Bluff deposits suggest a mid-Wisconsin age (mid-Würm) of about 25,000–48,000 yr (ref. 14). Five dates within this range have been obtained from deposits along the Georgia coast. Additional dates from this interval have been reported<sup>15,16</sup> from marine or deltaic sediments above, or not far below, present sea level. A retreat of glaciers is also reported at this time<sup>17</sup>. Stone implements of the Chelles-Acheul culture, believed to be middle to late Pleistocene in age, have been found in the gravels of the 5 m terrace<sup>9</sup>.

In both the Georgian and African areas there is evidence that the late Pleistocene shorelines developed following a fluctuation of the sea to a level below the next lower shoreline and usually an emergence was followed by a submergence of lesser magnitude than the previous one. In Georgia the transgressive relation of barrier island sands to lagoonal salt marsh deposits suggests emergence followed by submergence. The formation of barrier islands is also thought to necessitate some submergence<sup>18</sup>. In the African area streams associated with each sea level have eroded deep channels across the terrace which pre-dates the next lower terrace and indicates a level of erosion which extended below the sea level associated with the next lower terrace. There is little indication of the magnitude of the Georgian and African emergences except for the one following the development of the Silver Bluff shoreline (1.4 m) for which evidence from several areas suggests a lowering of sea level of as much as 100–105 m below present sea level<sup>15,19</sup>. There is no evidence for a "post-glacial" high stand of sea level along either the Georgia or South West Africa coast.

I thank Dr Charles G. Stocken for guidance in South West Africa. This research was supported by the US National Science Foundation.

## Effect of Crude Oil on the Nuclear Magnetic Relaxation of Water Protons in Sandstone

Brown and Fatt<sup>1</sup> have found that the nuclear thermal relaxation time,  $T_1$ , for water protons in contact with sand is shorter than for bulk water and is increased by placing an organic film on the surface. They have suggested that the enhanced relaxation arises from strong local magnetic fields caused by paramagnetic centres on the surface. The film would then act as a physical shield. The KST model<sup>2</sup> describes the effect of such paramagnetic centres as

$$\frac{1}{T_1} - \frac{1}{T_B} = \frac{V_s}{V_B} r_s$$

where  $T_1$  is the observed relaxation time;  $T_B$ , the bulk relaxation time;  $V_s$ , the volume of fluid near the surface relaxing with rate  $r_s$ ; and  $V_B$ , the volume of fluid relaxing at the bulk rate<sup>3</sup>.

A typical measurement on distilled water in natural sandstone, made by free induction at 3 kG, is shown in Fig. 1. For a homogeneous system the curve is expected to follow

$$M = A e^{-t/T_1}$$

where  $M$  is the magnetization,  $A$  is proportional to the number of nuclei, and  $t$  is time. Fig. 1 has two such components, each representing about half the interstitial water. By the KST model this would be interpreted as a bimodal pore size distribution.

In nuclear magnetic logging of oil wells the relaxation rate of water which has infiltrated the formation from the drilling mud is measured. In water zones a signal like the long phase of Fig. 1 is seen, while in zones bearing oil a two-phase signal is seen, with a short phase like that of the water zone and a long phase resembling bulk water<sup>4</sup>.

This information suggested that the presence of crude oil in sandstone reduces the extent to which the surface can influence water which later infiltrates the rock, and that adsorption of surface-active components from the oil may be the mechanism responsible. Alternatively, it was possible that the paramagnetic centres had been reduced by the oil; however, treatment of clean sandstone with hydrogen peroxide and with hydrazine solutions did not alter its behaviour. Exposure to either oxygen or hydrogen at elevated temperatures resulted in no signal at all, presumably because trace surface iron species were irreversibly transformed to the ferromagnetic state, which caused the magnetization signal to decay too fast to be seen. R. J. S. Brown has informed us that in these circumstances he has noted an increase in the ferromagnetization of the rock.

The effect of various surfactants is shown in Table 1; however, only the long phase of the signal is tabulated.

Fig. 1.

Fig. 2.

The surfactants were adsorbed from solution, and the solution was displaced with distilled water the relaxation of which was then measured. Approximate lengths for the surfactant molecules are shown. If, rather than zero, a molecular length of  $L = 3 \text{ \AA}$  is ascribed to the untreated system, these data are fairly well described by the expression

$$\frac{1}{T_1} - \frac{1}{T_B} = 6.3 L^{-1/2}$$

The value for the untreated rock corresponds to the thickness of a monolayer of water. A multitude of other expressions, such as  $T_1 = A + BL$  or  $T_1 = C - De^{-L}$ , are possible, but less appealing.

Table 1. EFFECT OF ADSORPTION ON  $T_1$ 

Adsorbate	$T_1$ (msec)	Molecule length ( $\text{\AA}$ )
Untreated	247	0
Methylene blue	316	4.5
Dodecylammonium acetate	470	15
Stearic acid	564	23

When clean sandstone was exposed to crude oil and then saturated with water, similar results were obtained. The magnitude of the effect depended on the exposure time; equilibrium required several days and yielded a  $T_1$  of about 1 sec (the  $T_1$  of bulk water  $\sim 2.3$  sec). This time was reduced if heat was applied during the exposure to oil. The bulk of the oil could be removed from the rock by thorough flushing with cyclohexane; this left only a tightly adherent residue that could be removed by washing with a chloroform-acetone solution and was analysed as asphaltene. Similar results were obtained whether the rock was water saturated or dry when the crude oil was introduced, which indicates either that the water was very effectively displaced, or that residual water was present in a thin film or in droplets that posed no barrier to asphaltene adsorption.

In one experiment the rock was only partially saturated with oil, the remainder being saturated with water. On flushing the rock with cyclohexane and saturating with water the relaxation curve in Fig. 2 was obtained. This is easily broken into the three indicated components.

The data show that the  $T_1$  of water in porous rock is increased by adsorption of large surfactant molecules on the surface and that this can occur when the rock is exposed to crude oil. The observed temperature effect is explained by the positive entropy change accompanying adsorption, as discussed by Moilliet *et al.*<sup>5</sup> Because of the viscosity of the crude oil, cyclohexane was sometimes used to remove the bulk oil from the rock before it was saturated with water. It was thought that this would not affect the distribution of adsorbed species as the washing

took place in minutes, and the time constant for adsorption was days.

The three components of the relaxation curve, Fig. 2, can be explained as follows: fast component, water in very fine pores; intermediate component, water in coarse pores; slow component, water in large pores that had been filled with oil and are thus coated with asphaltene. The experiment was quite analogous to the situation existing in an oil reservoir, in which some pores of the reservoir rock are largely filled with oil and some are largely filled with water. When the rock is flushed with water from the drilling mud a nuclear magnetic logging signal is seen from both types of pore, but the pores that have been exposed to oil have a long relaxation time. The very short signal, which represents fine pores, is not seen by the nuclear magnetic logging because of the limitations of the equipment used.

## PHYSICS

### Analysis of X-ray and Neutron Diffracted Intensities calculated for a Random Network Model of Vitreous Silica

EXPERIMENTAL diffraction patterns of vitreous silica are characterized by low density at the centre and a small number of diffuse maxima at small angles, which indicates that only short range order exists. This leads to two different interpretations of the structure of vitreous silica—first, that it consists of an irregular non-crystalline network of silicon and oxygen atoms and, second, that it consists of an aggregate of extremely tiny crystals<sup>1,2</sup>. We now describe the preliminary results of calculating X-ray and neutron diffraction intensities from an irregular non-crystalline network model of vitreous silica, the construction of which was described earlier<sup>3</sup>.

The intensity of coherent X-ray scattering from an array of atoms which is allowed to take all possible orientations in space is given by Debye's equation<sup>4</sup>

$$I(s) = \sum_n \sum_m f_n(s) f_m(s) \frac{\sin 2\pi s r_{nm}}{2\pi s r_{nm}} \quad (1)$$

where  $I(s)$  is the intensity in electron units diffracted at an angle  $\theta$ ,  $s = 2 \sin \theta / \lambda$ ,  $f_n(s)$ ,  $f_m(s)$  are the atomic scattering factors for the  $n$ th and  $m$ th atoms respectively and  $r_{nm}$  is the magnitude of the vector separating these two atoms. The scattering from the random network model was calculated by a direct application of this equation, in which the double summation includes terms referring to each pair of atoms in the model and, in particular ( $n=m$ ), terms referring to all atoms singly. The individual contribution of the silicon and oxygen atoms to the coherent scattering intensity is then  $N_{\text{Si}} f_{\text{Si}}^2(s)$  and  $N_{\text{O}} f_{\text{O}}^2(s)$ , respectively, where  $N_{\text{Si}}$  and  $N_{\text{O}}$  are the numbers of silicon and oxygen atoms in the network and  $f_{\text{Si}}(s)$  and  $f_{\text{O}}(s)$  are the corresponding atomic scattering factors. Using this notation, the intensity pattern as a whole may be rewritten as

$$I(s) = N_{\text{Si}} f_{\text{Si}}^2(s) + N_{\text{O}} f_{\text{O}}^2(s) + f_{\text{Si}}^2(s) \sum_{n,m} \frac{\sin 2\pi s r_{nm}}{2\pi s r_{nm}} + f_{\text{O}}^2(s) \sum_{n,m} \frac{\sin 2\pi s r_{nm}}{2\pi s r_{nm}} + f_{\text{Si}}(s) f_{\text{O}}(s) \sum_{n,m} \frac{\sin 2\pi s r_{nm}}{2\pi s r_{nm}} \quad (2)$$

In this equation, the first sum represents the contribution of pairs of silicon atoms, the second, the contribution of oxygen atoms, and the third, the contribution of silicon-oxygen pairs.

Using equation (2), the intensity of coherent scattering was calculated on the University of London Institute of Computer Science 'Atlas' Computer for a range of values of  $s (= 2 \sin \theta / \lambda)$  up to 1.8.

To the values of the coherent scattering intensities deduced from Debye's equation should be added values for the independent incoherent scattering intensities. The incoherent scattering intensity for an atom is given in electron units by

$$I_{\text{inc}}(s) = R(Z - \sum_i g_i^2(s))$$

where  $g_i(s)$  is the scattering factor for the  $i$ th electron in the atom,  $Z$  is the atomic number and  $R$  is a recoil factor, which for the purposes of this calculation may be taken as unity without too much error. Values of  $G_i(s) (= I_{\text{inc}}(s)/R)$  were taken from the *International Tables*. The total incoherent scattering for the vitreous silica model is given by

$$I_{\text{inc}}(s) = N_{\text{Si}} G_{\text{Si}}(s) + N_{\text{O}} G_{\text{O}}(s)$$

The total X-ray scattering, expressed in electron units, is plotted in Fig. 1 as a function of  $\sin \theta / \lambda$ . In the same figure experimental scattering curves taken from papers by Warren<sup>5</sup> and Zarzycki<sup>6</sup> are shown. The calculated

Fig. 1. X-ray scattering from a random network model of vitreous silica. (1) Total scattering (coherent plus incoherent); (2) total independent scattering; (3) incoherent scattering. Insets, experimental results from the work of A. Zarzycki<sup>6</sup>; B. Warren<sup>5</sup>.

Fig. 2. Components of X-ray diffracted intensity: (1) due to silicon-silicon pairs; (2) due to oxygen-oxygen pairs; (3) due to silicon-oxygen pairs.

Fig. 3. Neutron diffracted intensity from a random network model of vitreous silica. Insets, experimental results from the work of A. Carraro<sup>7</sup>; B. Egelstaff<sup>8</sup>.

scattering curve agrees quite well with the experimental curves, the most noticeable difference being in the height of the first peak. If atomic scattering factors for  $\text{Si}^{4+}$  and  $\text{O}^{2-}$  are used in place of those for the neutral atom, the height of the first peak approximates to that given by Warren<sup>5</sup> and Zarzycki<sup>6</sup>. In vitreous silica, however, the Si—O bond is thought to be only about 40 per cent ionic and therefore these ionization states are unlikely. Further computations, using different values for atomic scattering factors and using different temperature factors, are in progress.

Fig. 2 shows, also in electron units, components of the coherent intensity as calculated for (1) silicon pairs, (2) oxygen pairs and (3) silicon-oxygen pairs. This clearly reveals that each type of interaction contributes significantly to the total scattering throughout the whole pattern.

Values for neutron diffracted intensities (in barns) are plotted in Fig. 3. These were calculated from equation (2) by substituting the scattering lengths  $b_{\text{Si}} = 0.42 \times 10^{-12}$  cm and  $b_{\text{O}} = 0.577 \times 10^{-12}$  cm for the atomic scattering factors  $f_{\text{Si}}(s)$  and  $f_{\text{O}}(s)$ . The same figure includes experimental curves taken from the work of Carraro<sup>7</sup> and Egelstaff<sup>8</sup>, which have been corrected for multiple and incoherent scattering.

### Filtered Electron Diffraction Measurements from Thick Polycrystalline Metal Foils

DURING the past decade there have been considerable developments in high voltage electron microscopes and diffraction cameras which work reliably at voltages above 300 kV. These instruments are designed for studies of "thick" specimens—foils which it is practicable to prepare by cutting or thinning bulk materials. Metal specimens thinned from bulk are usually several thousand angstroms thick and, if examined at 100 kV, electrons which have been inelastically scattered fog the image or diffraction pattern. By working at much higher voltages the "contrast" of thick specimens is enhanced.

An alternative is to remove the loss electrons, and promising improvements of contrast in photographic instruments have been demonstrated<sup>1</sup>. Recently an automatic electron diffractometer designed by one of us has been applied to the study of thick polycrystalline films, with 50 kV electrons. Such instruments operate with filters capable of eliminating all electrons which have suffered more than a small energy loss—and are equipped with two-dimensional scanning, which is necessary for testing whether or not preferred orientation has been achieved.

Fig. 1 shows intensity profiles from an aluminium specimen 10,000 Å thick; the various profiles are obtained with different settings of the energy filter which gives

Fig. 1. Well-filtered intensity profiles from nearly randomly oriented polycrystalline aluminium foil of thickness 10,000 Å; 50 kV electrons.

Fig. 2. An unfiltered intensity profile from 10,000 Å thick aluminium foil. The intensity gain is reduced by a factor of 17.5 compared with Fig. 1. 50 kV. (Zero is off-scale.)

nearly zero transmission when set at  $-2$  V with respect to the cathode. It is possible to make an approximate comparison between well-filtered and unfiltered profiles, and this is given, for a different 10,000 Å aluminium foil, in Table 1.

The enormous proportion of loss electrons is evident from Table 1, and the proportion is still enormous at large scattering angles. If the comparison were made for angular positions corresponding with background rather than at diffraction rings, the proportion of loss electrons would be greater.

Fig. 2 shows the unfiltered profile of 10,000 Å thick polycrystalline aluminium. A "smooth background" has been interpolated and broad humps can be seen above the background, with aluminium rings superimposed on them. There are signs of these humps in the well-filtered curves, but their proportions are quite different. Clearly no quantitative measure of aluminium ring intensity can be obtained from the unfiltered profile; nor can any conclusions be drawn about the relative intensity of the aluminium rings without filtering.

The profiles of Fig. 1 do not look very different from the nearly elastic profiles of a thin aluminium film randomly oriented and diffracting kinematically. Table 2 shows, however, a comparison with the quantity  $\sqrt{i_{\text{peak}}/(p/s^2a^2)}$  and the atomic scattering function (ref. 2)  $f$  for aluminium.  $i_{\text{peak}}$  is the intensity above the interpolated background of Fig. 1 and the 2 eV profile,  $p$  is the multiplicity,  $s = 2 \sin \frac{1}{2} \beta/\lambda$ , and  $a$  is the lattice spacing. The  $\{111\}$  and  $\{200\}$

peaks show evidence of dynamic effects; nevertheless it is remarkable that there should be so little evidence of dynamic scattering in so thick a film. Unfortunately it is not possible, with so thick a film, to use the half width of the peaks as a rough measure of crystallite size.

Table 2. TEST FOR KINEMATIC SCATTERING CONDITIONS IN 10,000 Å ALUMINIUM FOIL

Peak	111	200	220	311	222	400	331	420	422
$\sqrt{\left(\frac{I_{\text{peak}}}{(p/s^2a^2)}\right)}$

Ratio	0.58	0.71	1.0	0.96	0.98	1.15	0.91	0.86	0.68

Similar measurements have been recorded with silver up to 1600 Å thick at 50 kV. The traces then show much quantum noise: this could, of course, be eliminated if a slower scan generator were available. All the silver films had considerable preferred orientation (as shown in Fig. 3) — a 1360 Å film with a 0.6 eV energy bandwidth. With silver films of this thickness the unfiltered profile shows very weak rings (invisible on the fluorescent screen) and the unfiltered background is about 100 times as intense as the 0.4 eV filtered one.

It has been claimed<sup>3</sup> that the great increase in transmission observed when silver specimens are cooled to 90° K is evidence of dynamic effects. The measurement supporting this statement was unfiltered and was from a 650 Å film at 30 kV. Our results indicate that unfiltered measurements from films of such a thickness mean little because there is a predominance of loss-electrons.

These nearly elastic measurements on thick films suggest that diffraction instruments, working at 100–150 kV, and equipped with efficient filters, would enable aluminium specimens 3–5 μ thick and steel foils thicker than 1 μ to be studied. The diffraction results also suggest that electron microscopes working between 100 and 150 kV, and using the successful filters which have been developed<sup>4</sup>, would be able to obtain filtered images of equally thick foils. With thick specimens the current elements may fall to 10<sup>-18</sup> amp on filtering, which would necessitate the use of image intensifiers to integrate quantum noise over periods of many seconds; improved stability and vacuum conditions would therefore be needed. The cost of these developments, however, would be small when compared with the cost of 1 MV instruments.

We thank the AEI Electron Microscopy Laboratory for providing the aluminium specimens of known thickness.

### Electron Spin Resonance Transitions Involving Simultaneous Changes in Spin States of up to Three Neighbouring Protons

OCCASIONALLY an electron spin resonance absorption line is accompanied by satellite lines of weak intensity. These satellite lines, arising from a change in spin state of a nearby nucleus concurrent with the change in spin state of the electron, were first observed in irradiated frozen acids<sup>1</sup>. A theoretical explanation for these transitions has been given by Trammell *et al.*<sup>2</sup>, who also predicted a second set of satellites corresponding to two neighbouring protons concurrently changing their spin state. Recently Snipes and Bernhard<sup>3</sup> observed such satellite lines in γ-irradiated single crystals of barbituric acid dihydrate. We report here experimental evidence of a second and even a third set of satellites corresponding to two and three neighbouring protons simultaneously changing spin state.

Atomic hydrogen was produced in 6 molar sulphuric acid with cobalt-60 γ radiation at 77° K (ref. 4). In the course of examining the microwave power saturation of the atomic hydrogen doublet, it was found that at very low microwave power levels the atomic hydrogen line was always accompanied by one satellite line on each side (Fig. 1a). On increasing the microwave power, the intensity ratio of the satellite line to the main transition line also increased, and a new set of satellite lines became visible (Fig. 1b). At an even higher power level and higher spectrometer sensitivity, a further set of lines of weak intensity was obtained (Fig. 1c). This observation was made at both the high field and low field lines of the hydrogen doublet. According to the theoretical treatment<sup>2</sup>, the spacing of a satellite to the main line and the intensity ratio are field dependent. Because the splitting of the hydrogen doublet is 505 G, different values for the splitting and intensity ratio are expected, and we can very easily compare the theoretical predictions with the experimental results.

To obtain correct values of the splittings and intensities of the various lines, electron spin resonance spectra of atomic hydrogen were recorded at 85°–90° K over a wide range of microwave power levels. The spectra were analysed by setting up a computer programme under the following assumptions to reduce the number of free parameters.

(i) Each line is represented by the derivative of a Gaussian curve with three adjustable parameters, the amplitude, splitting and width.

(ii) A spectrum is composed of four sets of lines corresponding to zero, one, two, and three simultaneous proton transitions. The sets contain, respectively, one line, two lines of equal intensity, three lines with intensity ratios 1 : 2 : 1, and four lines with ratios 1 : 3 : 3 : 1.

(iii) The splitting from the main transition per proton flip is a constant, independent of whether other protons are making simultaneous flips.

(iv) The line width is the same for all lines within each set.

The computer was then programmed using the method of Powell<sup>5</sup>. An example of a spectrum fit in this way is shown in Fig. 2. The agreement between the experimental and calculated curves is inferior in this case to that obtained with most of the other spectra. From the experimental spectra analysed by the computer values of splitting and line intensities were obtained. The splittings observed experimentally, at magnetic field strengths of 2,954 and 3,459 G are 4.56 and 5.3 G respectively, and compare favourably with the theoretically predicted values of 4.4 and 5.15 G respectively.

By releasing the constraint provided by assumption (iii) no significant improvement in the fits to the data was obtained, thus justifying this assumption.

The saturation behaviour of the different groups of lines is similar, following first the linear relation between microwave power and signal amplitude and then bending off, indicating that saturation takes place. These findings differ somewhat from the results reported by Snipes *et al.*<sup>3</sup>, who could not find saturation for the satellite lines even at high power levels. After correcting for the effect of saturation we determined the intensities of the various satellites relative to that of the main transition.

It is now possible to make an estimate of the average distance of the flipping protons from the electron spin density by using the following relation given by Trammell *et al.*<sup>2</sup>

$$\frac{T_1}{2T_0} = \frac{3}{20} \cdot \left( \sum_i \frac{g_e^2 \beta_e^2}{H^2 r_i^6} \right) \quad (1)$$

where  $H$  represents the applied magnetic field,  $r_i$  the distance of the  $i$ th flipping proton from the proton on which the spin density is concentrated,  $T_1$  is the intensity of the first satellite relative to the intensity of the principal transition  $T_0$ . Because the simultaneous flipping of a second proton is independent of the flipping of the first

Fig. 2. One half of the first derivative electron spin resonance tracing of the high field hydrogen line with its satellites (—) compared with the calculated spectrum (●).

proton and to a certain extent dependent on the number of microwave quanta present in the cavity, the ratio of the transition probabilities is given by a squared expression of the following form

$$\frac{T_2}{2T_0} = \left( \frac{3}{20} \right)^2 \cdot \left( \sum_i \frac{g_e^2 \beta_e^2}{H^2 r_i^6} \right)^2 \quad (2)$$

where  $T_2$  is the total intensity of the triplet due to the double proton flip. The outer line of that triplet represents only a quarter of the total intensity.

Accordingly we obtain an expression for the transition probability ratio of the third set of satellites and the principal transition line

$$\frac{T_3}{2T_0} = \left( \frac{3}{20} \right)^3 \cdot \left( \sum_i \frac{g_e^2 \beta_e^2}{H^2 r_i^6} \right)^3 \quad (3)$$

Here  $T_3$  is the total transition probability of the triple proton flip. The outermost line of the quartet due to the triple proton flip represents only an eighth of the total intensity.

Fig. 1. First-derivative electron spin resonance tracing of the hydrogen doublet of sulphuric acid glasses irradiated at 77° K and recorded at 90° K. The relative spectrometer sensitivity and microwave power level are increasing from top to bottom as indicated. New satellite lines are appearing with increasing microwave power.

Fig. 3. Microwave power saturation of the main transition and the different satellites of the high field hydrogen line.

Using the equations given here, the average distance ( $r$ ) to the protons changing spin state simultaneously with the electron was found to be 1.79 Å, 1.80 Å and 1.85 Å for the single, double and triple proton flip respectively. The results of the single proton flip are in good agreement with the value of 1.73 Å given by Trammell *et al.*<sup>2</sup>. Because the satellite intensity is proportional to  $1/r^6$  or powers thereof, only the nearest protons are

contributing to it. From these results we conclude that there are at least three nearest protons surrounding a hydrogen atom in the glassy material investigated at distances ranging from 1.79 Å to 1.85 Å.

### Hysteresis Experiments in Rheology

THE value of "normal" hysteresis experiments in rheology was recently discussed by Harris<sup>1</sup>, who observed that hysteresis loops could be obtained even with Newtonian fluids and that steady oscillatory experiments were therefore to be preferred for materials which exhibit the effect of thixotropy because of the simpler analysis. It should be remembered, however, that steady oscillatory experiments cannot yield information on thixotropic fluids when their resistance to flow is near maximum. A thixotropic fluid is defined here as a fluid which exhibits an isothermal, time dependent resistance to flow at constant rate of shear. For the case when the fluid is contained between concentric cylinders the condition offering near maximum resistance to flow can be studied by the method of Billington and Huxley<sup>2,3</sup>, in which a near instantaneous drive is applied to, for example, the outer cylinder, which is then maintained at constant angular velocity, and the resulting motion of the inner cylinder moving against the restoring couple of the measuring head is observed.

For a Newtonian fluid the governing equation for the motion of the inner cylinder, neglecting friction, is

$$I\ddot{\theta}_i + C\dot{\theta}_i + K\theta_i = C\Omega_0 \quad (1)$$

where  $I$  is the moment of inertia of the inner cylinder,  $K$  the restoring couple per unit angular displacement of the torsion head,  $\theta_i$  the angular displacement of the inner

Fig. 1. Transient rise and decay of the deflection of the inner cylinder for a Newtonian oil.

Fig. 2. Instantaneous shear stress—rate of shear graph for a Newtonian oil showing zero hysteresis. (Open symbols from rise; solid symbols from decay.)

cylinder,  $\Omega_0$  the speed of rotation of the outer cylinder and  $C$  is given by

$$C = \frac{4\pi\mu r_i^2 r_0^2 h}{r_0^2 - r_i^2} \quad (2)$$

where  $\mu$  is the viscosity,  $r_0$  the radius of the outer cylinder, and  $r_i$  and  $h$  are the radius and height of the inner cylinder respectively. Billington<sup>4</sup> considered the solution to equation (1) for the case when  $(C/2I)^2 \gg K/I$  and with the boundary conditions  $\theta_i = 0$  at  $t = 0$  and  $\dot{\theta}_i = \Omega_0$  at  $t = 0$ , which were verified by experiment, obtained the solution

$$\theta_i = \theta_i(\infty) \left( 1 - \exp \left[ -\frac{t}{\tau_\mu} \right] \right)$$

where

$$\theta_i(\infty) = \frac{C\Omega_0}{K} \quad (3)$$

and

$$\tau_\mu = \frac{C}{K}$$

If, after an infinite time, the motion of the outer cylinder is suddenly brought to rest, the corresponding solution to equation (1) with  $\Omega_0 = 0$  and the boundary conditions  $t = 0$ ,  $\theta_i = \theta_i(\infty)$  and  $\dot{\theta}_i = -\Omega_0$  is given by

$$\theta_i = \theta_i(\infty) \exp \left( -\frac{t}{\tau_\mu} \right) \quad (4)$$

Equations (3) and (4) for the transient rise and decay of the deflection of the inner cylinder, resulting from the near instantaneous application of the drive to the outer cylinder and then subsequently bringing this cylinder suddenly to rest, form quasi-steady solutions as can be verified by differentiation. Fig. 1 shows a trace of part of a transient rise and decay curve so obtained with a fluid of viscosity

$$\mu = 24.8 \text{ P. and } (C/2I)^2 \sim 10K/I$$

The quasi-steady solutions for the transient rise and decay can therefore be taken to form a "natural" cycle of shear which is distinguished from "normal" forced cyclic shearing in which the angular velocity of the outer cylinder is increased from zero to a given value at a uniform rate and then subsequently decreased to zero at the same rate. For the condition  $(C/2I)^2 \gg K/I$  both a forced shearing cycle and the natural shearing cycle, described here, give zero hysteresis loops to a sufficient approximation for Newtonian fluids, although complex phase relations arise when this condition is not satisfied. Fig. 2 shows a zero hysteresis loop of shear stress plotted against

rate of shear calculated from the relative angular velocity of the cylinders  $\Omega_0 - \dot{\theta}_t$  for a natural cycle of shear.

A distinction is made between the natural and forced cycles of shear because terms involving the rate at which the speed of the outer cylinder is changed do not arise in the former case. It will therefore assume importance for thixotropic fluids because it should be possible to study the flow properties in a condition closer to that offering maximum resistance to shear. Some results for lubricating greases have been obtained in this way<sup>5</sup>.

## MOLECULAR STRUCTURE

### Sequence Similarities between Hen Egg-white and *T*<sub>4</sub> Phage Lysozymes

Inouye and Tsugita<sup>1</sup> have reported the sequence determination of *T*<sub>4</sub> phage lysozyme and remark that "no common first order structure is found between *T*<sub>4</sub> phage lysozyme and hen egg-white lysozyme, but the distribution of basic, acidic and hydrophobic amino-acids seems to be similar".

By employing the known structure of hen egg-white lysozyme<sup>2</sup> and the following guiding principles, a more definite correlation between the two sequences may be suggested. (a) The shorter egg-white lysozyme chain has evolved from a molecular species more like *T*<sub>4</sub> lysozyme by the deletion of about thirty-one residues (compare the deletion of residues in passing from myoglobin to haemoglobin). (b) The above principle implies that *T*<sub>4</sub> and egg-white lysozymes exert their catalytic function in a similar way so that residues implicated directly in the action of egg-white lysozyme must be present in broadly similar positions in *T*<sub>4</sub>. (c) The comparison of haemoglobin sequences<sup>3</sup> suggests that deletion from alpha-helical regions will be relatively uncommon, because it will usually disturb the environment of all later members of the helix to a serious degree. Where it does occur it should involve deletions corresponding to one or more turns of the helix. (d) The critical importance of hydrophobic groups in internal sites of proteins particularly indicated by the analysis of haemoglobins and myoglobin<sup>4</sup> suggests that hydrophobic internal residues of egg-white lysozyme, particularly at the *N*-terminal end where they may be required to act as a nucleus or "internal template" for folding<sup>5-7</sup>, will have their counterparts in *T*<sub>4</sub> phage lysozyme. (e) Common identical residues can be considered to be significant only if several can be brought into correspondence without the need for deletions between individual common residues. (f) Residues in *T*<sub>4</sub> and egg-white lysozymes related by a single base change of their codons can be regarded as less significant than those related by the above principles, for most amino-acids are removed in the code from others by only two base changes, and, in the long period of evolution separating the molecular species, reversals of base changes and even complete cycles of all three base changes may have occurred to confuse the issue. When, however, single base changes suggest one choice from several arrived at on these grounds, they may be useful. (g) In a similar way common charged residues, polar residues and small residues are regarded as of secondary importance, but may enhance the choice made on other grounds.

Table 1 shows a correlation between the egg-white and *T*<sub>4</sub> sequences made on the basis of these principles with the order of priorities indicated. It is not yet possible to weight each of the above factors in precise numerical terms and the analysis centres upon establishing qualitatively that one relationship between the chains uniquely satisfies them. Otherwise, despite a high index

H denotes hydrophobic residues common to both; p, polar residues; s, small residues; - and +, residues which may be negatively charged and residues which may be positively charged; in each instance common to both sequences. 1 denotes a single base change separating the two residues and common residues are underlined.  $\alpha$ -Helix is indicated by vertical brackets.

of common features it may seem that some other sequence relationship would be equally favourable.

The most important restriction, that concerning the activity of lysozymes, is that residues analogous to egg-white lysozyme residue 35, a glutamic acid, and to residue 52, an aspartic acid, must be found because these residues are essential for activity according to the present evaluation of the binding of competitive inhibitors to crystalline lysozyme<sup>8</sup>. Only one carboxylic acid residue, aspartic acid 47, is present in the  $T_4$  chain between residues 25 and 50. There are five carboxylic acid residues between residues 50 and 75, but only the  $T_4$  residues 47 and 64 can be brought into correspondence with egg-white residues 35 and 52 without deletions between them. This choice reverses the position of aspartic and glutamic acids in the active site. It is strengthened by the triple correspondences of egg-white 31, 32, 33 with  $T_4$  41, 42, 43, and of egg-white 54, 55, 56 with  $T_4$  77, 78, 79, which suggest outside limits for the comparison of these regions of the two sequences. If deletion is permitted between the two active carboxyl groups it is possible to bring the aspartic acid residue 52 of egg-white into correspondence with the aspartic residues 70 or 72 of  $T_4$ . The latter possibility illustrates the limitation of the present comparison. The principles enunciated cannot always decide between minor variants within the broad overall correlation which does, however, appear to have a strong claim to being of the unique kind sought. Part of the interest in making a prediction before further lysozyme sequences are known is that, when they are established and the eye can immediately see straight-forward correspondences, it will be even more difficult to assess the real factors which must remain common to evolving structures.

The correspondence, particularly at the  $N$ -terminal end, is good so far as each of the stated principles is concerned, thus: internal residues of egg-white lysozyme are in general replaced by other hydrophobic groups in corresponding positions of  $T_4$ ;  $\alpha$  helix is not interfered with in the first  $\alpha$ -helix and only marginally in the second; single base changes account for any amino-acid changes in twenty of the first thirty residues.

The frame shift mutant of  $T_4$  phage examined by Terzaghi *et al.*<sup>9</sup> would involve the replacement of four residues in the second  $\alpha$ -helix: ser, pro, ser, leu, asp by val, his, his, leu, met. The rules which have been put forward to predict  $\alpha$ -helical sections by Guzzo<sup>10</sup> and Prothero<sup>11</sup> would suggest that  $\alpha$ -helicity need not be interfered with. The possession of an extra  $N$ -terminal methionine by  $T_4$  phage lysozyme, according to the sequence relationship

suggested, may be significant in terms of current theories of chain initiation.

### Crystal Structures of the Lamellar Calcium Aluminate Hydrates

THE compound  $\text{Ca}_2\text{Al}(\text{OH})_7 \cdot 3\text{H}_2\text{O}$ , or  $4\text{CaO} \cdot \text{Al}_2\text{O}_3 \cdot 13\text{H}_2\text{O}$ , and several of the many related basic salts, are important because they are formed on hydration of cements<sup>1</sup>. These substances form platey crystals, which are hexagonal or pseudohexagonal, with (0001) cleavage. The unit cells of some are known, but no crystal structures have been determined. This can be attributed, at least in part, to the poor quality of the crystals, which are rarely more than  $100\mu$  across and a few microns thick, and which often show disorder in both orientation and stacking.

We have partially determined the structure of a crystal which approximated in composition to  $\text{Ca}_2\text{Al}(\text{OH})_7 \cdot 3\text{H}_2\text{O}$  with some structural  $\text{CO}_3^{2-}$ , and which may have been a polytype of hydrocalumite ( $\text{Ca}_{18}\text{Al}_8(\text{OH})_{54}(\text{CO}_3)_2 \cdot 21\text{H}_2\text{O}$  approximately).

X-ray photographs of single crystals indicated that the crystals were trigonal, with  $a_H$  5.73,  $c_H$  47.16 Å, space group  $R3c$  or  $R3c$  and  $Z=6$ . This is analogous to the cell found for  $\beta\text{-Ca}_2\text{Al}(\text{OH})_6\text{Cl} \cdot 2\text{H}_2\text{O}$  by Kuzel<sup>2</sup>. The intensities of 146 independent reflexions were determined using a Hilger automatic linear diffractometer; partial corrections for absorption were applied as mentioned by Arndt, North and Phillips<sup>3</sup>. Intensity statistics indicated a centre of symmetry, and the space group was therefore taken to be  $R3c$ . The unit cell is composed of six layers

Fig. 1. Diagram of parts of the structure, seen in projection along the  $c$ -axis;  $z$  co-ordinates are given as fractions of the single layer thickness of 7.86 Å. A, Basic layer with Al at  $z=0$ ; B, interlayer region around  $z=1/3$ ; C, basic layer with Al at  $z=1$ .

lying perpendicular to *c*. Each layer is 7.86 Å thick in the *c*-direction and contains a single formula unit. If the structure of a single layer can be determined, the stacking of the layers, and thus all remaining features of the structure, follow from the space group.

The main features of the structure were determined from a three-dimensional Patterson synthesis, followed by Fourier and difference syntheses. The parameters have so far been refined to give  $R=0.16$ ; isotropic temperature factors were used, and unobserved reflexions were taken as having one half the structure amplitudes of the weakest ones observed. With some reservations, the results confirm the hypothesis of Buttler, Dent Glasser and Taylor<sup>4</sup> that these substances have structures based on mixed octahedral layers of composition  $\text{Ca}_2\text{Al}(\text{OH})_6$ , between which lie the water molecules and remaining anions.

Fig. 1 shows the essential features of the structure. The basic layers (Fig. 1A and C), which are composed of  $\text{Ca}_2\text{Al}(\text{OH})_6$ , lie in the *ab*-plane and occur at intervals of 7.86 Å in the *c*-direction. Comparison of Figs. 1A and C shows the stacking relation between adjacent layers. The basic layers are of ordered structure, and may be described either as distorted octahedral layers in which  $\text{Ca}^{2+}$  and  $\text{Al}^{3+}$  are regularly arranged, or alternatively as agglomerates of  $\text{Ca}^{2+}$  and  $\text{Al}(\text{OH})_6^{3-}$  ions. The interlayer regions (Fig. 1B) appear to be only partly ordered, with atoms statistically distributed among a number of sites; our results for these regions are tentative. The oxygen atoms at the sites marked *P* probably belong to water molecules, and raise the calcium co-ordination to seven. The remaining water molecules, hydroxide and carbonate ions, occupy the cavities centred on sites of the type marked *X*. The carbon atoms probably occur at *X*, and the oxygen atoms chiefly at or near sites of the type marked *Q*. A high proportion of the *P* sites appears to be occupied, and over half of the *Q* sites. Some oxygen atoms may also occur on the *X* sites.

The basic layers shown in Figs. 1A and C almost certainly occur in all members of the group, and the water molecules at the *P* sites probably occur in most of them. The essential differences between these substances lie therefore in the interlayer regions, and especially in the contents of the cavities previously mentioned. Variations in the type of layer stacking also occur, extremes of two and twelve layer arrangements having so far been reported<sup>1,2</sup>.

We thank Dr L. D. Glasser for helpful discussions, and Miss L. Hardman for obtaining the intensity data.

### Actinide Chelates: Uranium (IV) *N,N*-Diethyldithiocarbamate

THERE is at present intense interest in the co-ordination of sulphur to metal ions, especially those of the *d*-transition series<sup>1</sup>. Many of these complexes have unusual physical, chemical and structural properties. Little is known, however, about the co-ordination of sulphur to the actinide metal ions, and we report here preliminary observations on the first uranium (IV) complex with a sulphur chelate. The ligand, *N,N*-diethyldithiocarbamate (dte), has itself been widely used in the earlier transition metals (many of the known complexes are listed in ref. 2) in which, for example, the apparently simple complexes  $M(\text{dte})_2$  ( $M(\text{II})$  = chromium, manganese, iron, copper and zinc) actually involve 5-co-ordination<sup>3</sup>.

A variety of uranium (VI) disubstituted dithiocarbamates are known<sup>4,5</sup> and are in fact the ultimate products when uranium (IV) chloride is reacted with the ligands in the presence of air. In such reactions, a green, light sensitive intermediate compound, postulated to be  $\text{U}(\text{S}_2\text{CNR}_2)_4$ , is observed<sup>5</sup>. The pure uranium (IV) compound of the diethyl derivative is made by reacting stoichiometric quantities of uranium (IV) chloride with the sodium salt of dte in dry ethanol in an inert atmosphere. The ethanol is quickly removed under vacuum at room temperature and the product recrystallized from dry benzene as yellow, air sensitive plates which are stable indefinitely when stored in argon. (Analysis: found, U, 28.4; required for  $\text{U}[\text{S}_2\text{CN}(\text{C}_2\text{H}_5)_2]_4$ , U, 28.64 per cent.) Addition of ether or isopentane to the benzene solution increases the yield to almost quantitative proportions. The complex decomposes if left in contact with alcohol and solutions in benzene or methylene chloride are particularly sensitive to traces of oxygen.

Ebullioscopic measurements in benzene gave an average molecular weight of 812 compared with the monomeric  $\text{U}(\text{dte})_4$  unit of 831. It appears likely therefore that the uranium atom is eight co-ordinated to sulphur, raising the question of the stereochemistry about the uranium. Single crystal X-ray diffraction photographs obtained using Precession and Weissenberg cameras established that the lattice belongs to the monoclinic system with  $a=19.05$  Å,  $b=11.67$  Å,  $c=16.03$  Å and  $\beta=63^\circ 35'$ . Simple flotation experiments pointed to a density of between 2 and 3 and therefore the cell probably contains six molecules, giving a calculated density of 2.58. Observed reflexions, for  $hkl$ ,  $h+k=2n$ , for  $h0l$ ,  $h=2n$ , and for  $0k0$ ,  $k=2n$ , showed the probable space group to be  $C2/m$  ( $C^{2h}$ ). It is anticipated that intensity data will be collected and the complete structure solved.

Magnetic and spectral properties of  $\text{U}(\text{dte})_4$ , together with the synthesis and properties of analogous tetravalent actinide complexes ( $M(\text{IV})$  = thorium, protactinium, neptunium and plutonium), are now being investigated. These studies will be extended to include other sulphur, nitrogen and oxygen chelates.

*Note added in proof.* The preparation and infra-red spectra of the uranium (IV) and some allied actinide (IV) dithiocarbamates were reported at the 153rd ACS meeting, Miami, Florida, in April 1967 by J. P. Bibler and D. G. Karracker (Abstract L32).

### New Structures from the Dehydrogenation of Model Compounds related to Lignin

MANY natural products are now known to originate through coupling of free radicals formed by the oxidative dehydrogenation of phenols<sup>1,2</sup>. That this applies to plant lignins is now widely accepted. Much of our present knowledge of the chemical structure of lignin was developed over the past 20 years by the outstanding work of Freudenberg<sup>3</sup> and his associates, who showed that coniferyl alcohol and other *p*-hydroxycinnamyl alcohols are the principal precursors. They have identified more than forty compounds produced initially in the reaction, coupling having taken place through the phenolic oxygen, the position *ortho* to it in the aromatic ring or C-β of the side chain.

We have dehydrogenated simpler compounds, principally without C=C conjugation in the side chain, because many of the dehydrogenation products formed from coniferyl alcohol are of this type.

Previous experiments<sup>4-6</sup> on the limited dehydrogenation of lignin-related model compounds with hydrogen peroxide plus peroxidase showed that guaiacols, substituted in the 4-position with an alkyl side chain, gave rise by free-radical phenol coupling to dehydrodimers, principally the *o,o'*-dihydroxybiphenyl compound and a diphenyl ether. More pertinent models with an  $\alpha$ -carbonyl or hydroxyl group gave the related biphenyl compounds and other products not then identified. These have now been further investigated with surprising results.

Propioguaiacone was dehydrogenated in aqueous solution with hydrogen peroxide in an amount calculated to remove one atom of hydrogen per molecule; the reaction products comprised 60 per cent of the biphenyl, 16 per cent of the starting compound, and 24 per cent of a "resin". This resin showed a pronounced band in the infra-red spectra corresponding to the ester of an aliphatic acid. It consists principally of an amorphous trimer I.

Presumably one of the phenolic groups in the *o,o'*-dihydroxybiphenyl dehydrodimer is attacked and the mesomeric *cyclohexadienone*-type radical formed pairs with a monomeric *ortho* radical. This is followed by re-aromatization of the dienone ring by nucleophilic attack on its side chain carbonyl group by the phenoxyl ion formed by deprotonation of the upper unit. The product (I) contains two structural features that are novel in phenol coupling reactions: the aryl ester group and the biphenyl bond between the two right-hand aromatic residues, which is formed in an orientation that is *ortho*, *para'* to the original phenolic hydroxyls.

The extent of this unusual reaction is probably limited by the separation of much of the *o,o'*-dihydroxybiphenyl compound in its comparatively unreactive crystalline state. If the reaction is carried out in aqueous alcohol or acetone, more than twice as much ester is formed. A small amount

of the dimer represented by the two right-hand rings of (I) was found as well as the dimer (II). The latter is formed by a straightforward coupling mechanism, but the formation of the former must also involve this novel side chain transfer.

The new reaction appears to be quite general, vanillin and acetovanillone giving esters which can be detected by infra-red spectroscopy or by determination of the volatile acid produced by hydrolysis of the acyl group. Ethyl vanillate gives a product showing a strong aliphatic ester band in the infra-red, presumably the ethoxycarbonyl derivative of the phenol, that is, the product is an aryl ethyl carbonate.

The presence of ester groups in lignin has been claimed from time to time<sup>7</sup> but has usually been thought to be part of the extractive component of the plant or, if in the lignin, to have been the result of secondary esterification of the lignin with *p*-hydroxycinnamic acids<sup>8</sup>. These experiments suggest that ester groups may also be an intrinsic part of the polymeric system of the lignin.

If  $\alpha$ -ethylvanillyl alcohol is dehydrogenated enzymatically in aqueous solution, it is remarkable that when only 2-3 per cent of the calculated equivalent of peroxide is added, an odour of propionaldehyde is plainly evident. This propionaldehyde is also formed by release of the side chain from some molecules after coupling of *cyclohexadienone* radical forms. One oxidation product, the crystalline compound (IV) with a melting point 198°-200° C, can be isolated from the reaction mixture in high yield. The mode of its formation from biphenyl-linked dehydro-

dimers shown here illustrates the mechanism involved in the release of the propionaldehyde.

If 2:1 equivalents of peroxide are added and the propionaldehyde is collected and estimated, it corresponds to 83 per cent of the product referred to here. The reaction must proceed through the coupling of a dienone radical of one biphenyl group to the phenoxy radical of a second. This is then re-aromatized by expulsion of the side chain as aldehyde to give compound (III) which is further dehydrogenated to (IV).

The dibenzo [*d,f*] [1,3] dioxepin (IV) readily breaks up into coloured products when it is treated with dilute mineral acid or alkali at room temperature; these colours are reminiscent of those that develop more slowly in extracted wood meal on similar treatment. An analogous dioxepin structure has been noted by Hewgill<sup>9,10</sup> in products of the dehydrogenation of sterically hindered phenols used as food antioxidants.

As with the carbonyl compounds, this reaction also appears to be rather general, formaldehyde being detected in the case of vanillyl alcohol and acetaldehyde with apocynol. Once isolated and crystallized, the biphenyl compound from  $\alpha$ -ethylvanillyl alcohol proved immune to further dehydrogenation with peroxide-peroxidase in aqueous alcohol or acetone, possibly because of strong hydrogen bonding, but responded readily in dilute aqueous solution.

The dehydrogenation with peroxide-peroxidase of the frequently used and important lignin model guaiacyl-glycerol- $\beta$ -guaiacyl ether is now under investigation.

## CHEMISTRY

### Mössbauer Spectra of Some Iron 1,2-Dithiolenes

IRON forms a variety of complexes with 1,2-dithiolene ligands, for example,  $[\text{FeS}_4\text{C}_4\text{R}_4]_n^{2-}$  ( $z=0, -1, -2$ ;  $n=1$  or 2),  $[\text{Fe}(\text{NO})\text{S}_2\text{C}_4\text{R}_4]_n^{2-}$  ( $z=+1, 0, -1, -2$  or  $-3$ ) and  $[\text{FeS}_6\text{C}_6(\text{CN})_6]^{2-}$  (refs. 1-3), the structure and electronic configuration of which is uncertain. Mössbauer spectroscopy provides a means of obtaining such information<sup>4</sup>, and we report here the results of a preliminary investigation of some of these iron 1,2-dithiolenes.

The chemical shifts, shown in Table 1, are in the region expected for low-spin iron compounds and the large quadrupole splittings indicate considerable electric field gradients at the nucleus. The complex  $[(\text{C}_6\text{H}_5)_4\text{P}]_2[\text{FeS}_4\text{C}_4(\text{CN})_4]$  (two unpaired electrons) which contains the iron atom in the formal oxidation state +4, may be reduced to  $[(\text{C}_6\text{H}_5)_4\text{P}]_2[\text{FeS}_6\text{C}_6(\text{CN})_6]$  (one unpaired electron), in which the oxidation state may be regarded

Table 1. MÖSSBAUER DATA FOR SOME IRON 1,2-DITHIOLLENES

		0.47	1.27

\* The percentage of absorption was too low to yield reliable data.

formally as +3. The increase in chemical shift on this reduction confirms the decrease in metal oxidation state.

The large quadrupole splitting is the result of distortion from a regular octahedron to either  $D_3$  or  $D_{3h}$  symmetry which lifts the degeneracy of the  $t_{2g}$  orbitals, thus causing an electron imbalance in these orbitals. Relatively little change in the quadrupole splitting occurs on changing the overall charge of the complex from  $-2$  to  $-3$ . Perhaps this is to be expected because one electron outside the symmetric half-filled  $t_{2g}$  levels (that is,  $t_{2g}^4$ ) will have much the same field gradient as a single vacancy in the complete subshell (that is,  $t_{2g}^5$ ). There should, however, be a change in the sign of the field gradient and we hope to investigate this point further.

An X-ray crystal structural investigation of  $[(n\text{-C}_4\text{H}_9)_4\text{N}][\text{FeS}_4\text{C}_4(\text{CN})_4]$  (ref. 5 and I. Bernal, personal communication) has revealed that the anion is dimeric, each iron being surrounded by five sulphur atoms in a distorted square pyramidal arrangement with edge sharing. There is one unpaired electron per iron atom and these electrons are coupled antiferromagnetically. The spectrum of  $[(\text{C}_6\text{H}_5)_4\text{N}][\text{FeS}_4\text{C}_4(\text{CN})_4]$  is similar to that of the  $[(n\text{-C}_4\text{H}_9)_4\text{N}]^+$  salt and the Mössbauer parameters for this compound and  $[(\text{C}_6\text{H}_5)_4\text{N}][\text{FeS}_4\text{C}_4(\text{C}_6\text{H}_5)_4]$  indicate that both these compounds are dimeric. The Mössbauer spectrum of  $[(\text{C}_6\text{H}_5)_4\text{P}][\text{Fe}(\text{pyridine})\text{S}_4\text{C}_4(\text{CN})_4]$  is also similar to the simple dithiolenes, thus indicating that the complex is five co-ordinate but monomeric; J. A. McCleverty, J. Locke and N. Connelly have obtained magnetic measurements which indicate that this complex has three unpaired electrons (unpublished).

The decrease in chemical shift in the nitrosyl complex series, in comparison with the other five co-ordinated species, is to be expected because back-donation to the empty antibonding orbitals on the NO reduces the shielding of the  $4s$  electrons, increases the  $s$  electron density at the iron nucleus, and decreases the isomer shift. A reduction in the quadrupole splitting is also observed which indicates a more symmetric environment around the iron atom than in the other species. Dimerization of the nitrosyls by way of  $\text{Fe} \cdots \text{S}$  interactions to give six co-ordinated iron complexes is possible but, in view of the extensive polarographic and spectral evidence (the latter both in the solid and in solution) obtained by N. M. Atherton and his colleagues (unpublished), this is unlikely.

On the basis of recent analytical evidence, the compound originally formulated as  $[\text{Fe}(\text{NO})\text{S}_2\text{C}_2(\text{C}_6\text{H}_5)_2]_2$  is now formulated as  $[\text{Fe}_2(\text{NO})_2\text{S}_6\text{C}_6(\text{C}_6\text{H}_5)_6]$ . The Mössbauer spectrum consists of two overlapping, quadrupole split, absorptions indicating that there are two distinct iron sites, one of which has very similar parameters to those of the neutral five co-ordinate nitrosyl complex  $[\text{Fe}(\text{NO})\text{S}_4\text{C}_4(\text{C}_6\text{H}_5)_4]$ . The intensities of the two Mössbauer absorptions are approximately equal, but until definitive X-ray

structural data are available we can make no predictions about the structure of this molecule.

## HAEMATOLOGY

### Haemoglobin Sydney: $\beta 67$ (EII) Valine $\rightarrow$ Alanine: an Emerging Pattern of Unstable Haemoglobins

SEVERAL abnormal haemoglobins have recently been found in patients with inclusion body haemolytic anaemias<sup>1</sup>, and have been called unstable because they form precipitates more readily than haemoglobin A when warmed to 50° C. We now report the identification of the structural abnormality in one of these haemoglobins—haemoglobin Sydney—the haematology and the family study of which have already been described<sup>2</sup>.

Blood was obtained from a mother and her son of German (Hamburg) origin who had migrated to Australia. They had a family history of haemolytic anaemia and it was possible to produce red cell inclusion bodies after 48 h incubation. A haemoglobin fraction precipitable by heat was also present. Haemoglobin electrophoresis on paper using *tris* buffer<sup>3</sup> and in starch gel with discon-

Fig. 1. Paper electrophoresis of the haemoglobin of the propositus. The fraction separating between haemoglobin A and haemoglobin A<sub>2</sub> has been used for preparative work. Ultracentrifugation of the whole haemolysate showed that all fractions had the same sedimentation rate as haemoglobin A.

Fig. 2. Starch gel electrophoresis of the haemoglobin of the propositus (left) and of a control (right).

tinuous *tris*-citrate borate buffer at pH 8.6 (ref. 4) demonstrated the presence of a slow moving fraction and another fraction in the position of free  $\alpha$  chains (Figs. 1 and 2). The slow moving fraction was assumed to represent the abnormal haemoglobin, and purification of it was attempted by repeated paper electrophoresis at pH 8.9, as was used for haemoglobin Köln<sup>5</sup>. After five repeated separations, however, haemoglobin A was still present and it was decided to use the fraction as it was for chemical analysis. The finding of free  $\alpha$  chains suggested that, as in some other unstable  $\beta$  chain abnormal haemoglobins<sup>5-7</sup>, the present abnormal haemoglobin was again an unstable haemoglobin with its abnormality in the  $\beta$  chain. This could not be confirmed by hybridization of the haemoglobin with canine haemoglobin<sup>8,9</sup> because precipitation occurred when the pH was lowered to 4.7. Bands with the mobility of normal  $\alpha$  and  $\beta$  chains were found when the globin chains were examined by electrophoresis in starch gel with 6.5 molar urea at pH 8.6 (ref. 10). Similar results had been obtained with haemoglobin Köln and with haemoglobin Genova<sup>7</sup> and had indicated that any change in amino-acid composition of the globin did not in itself involve a change in charge. The likely abnormality was therefore an amino-acid substitution in the  $\beta$  chain involving uncharged amino-acids.

Examination of the globin, and separation and examination of the isolated chains of the globin, were carried out as summarized in refs. 5 and 7. The isolated  $\alpha$  and  $\beta$  chains were hydrolysed in 6 normal hydrochloric acid for 36 and 72 h and the results of amino-acid analysis compared with those of haemoglobin A. The composition of the  $\alpha$  chains of haemoglobin Sydney was normal, but the  $\beta$  chain showed a consistent increase in its alanine content with a corresponding decrease in valine.

Fingerprints of the tryptic digest of whole globin and of the isolated  $\alpha$  and  $\beta$  chains showed a normal pattern with the exception of two extra peptides which were consistently present—one just beneath  $\beta$ Tp IX and the other just beneath  $\beta$ Tp VIII-IX. Both these extra peptides gave a positive reaction for histidine and, as is shown in Figs. 3 and 4, they both had the same electrophoretic mobility as  $\beta$ Tp IX and  $\beta$ Tp VIII-IX at pH 3.5 as well as at pH 6.5. Because it was known that the haemoglobin under examination contained some normal

haemoglobin, it seemed likely that in haemoglobin Sydney a hydrophobic residue had been substituted by a less hydrophobic one in peptide  $\beta$ Tp IX. This would explain why the peptide pairs moved with the same electrophoretic mobility but with different chromatographic mobilities—the upper peptides being derived from haemoglobin A, the lower from haemoglobin Sydney. A curious feature of the fingerprint was that the upper peptide stained more deeply with ninhydrin than the lower in the case of the  $\beta$ Tp VIII-IX pair but that the reverse was true for the  $\beta$ Tp IX peptides. The intensity of the colour with ninhydrin is largely dependent on the N-terminal residues which in both the VIII-IX peptides must be lysine. The reversal of intensities observed in the pair of  $\beta$ Tp IX peptides indicates a difference in the N-terminal residues, particularly as valine, the N-terminal of  $\beta$ Tp IX, is known to stain poorly with ninhydrin.

Table 1. ANALYSIS OF PEPTIDES  $\beta$ Tp IX AND VIII-IX OF Hb SYDNEY AND Hb A

	$\beta$ Tp IX			$\beta$ Tp VIII-IX		
	Sydney	Hb A	Expected	Sydney	Hb A	Expected
Asp	2.6	2.5	3	2.6	2.3	3
Ser	1.0	0.9	1	1.2	1.3	1
Gly	1.9	1.9	2	2.0	2.2	2
Ala	3.2	2.2	2	3.0	1.9	2
Val	0.3	1.1	1	Nil	1.2	1
Leu	4.0	3.8	4	3.9	3.7	4
Phe	1.1	0.8	1	0.7	1.0	1
His	1*	1*	1	1.1	1.0	1
Lys	1*	1*	1	2.1	2.2	2
$\mu$ mole yield per residue	0.08	0.04		0.006	0.014	

\* A positive colour test was considered to represent one residue.

Table 2

Peptide	VIII				IX			
Hb A	Lys	Val	Leu	Gly	Ala	Phe	Ser---	Leu Lys
Hb Sydney	Lys	Ala	Leu	Gly	Ala	Phe	Ser---	Leu Lys
$\beta$ -chain residue	66	67	68	69	70	71	72	81 82
Helical notation	E10	E11	E12	E13	E14	E15	E16	EF5 EF6

This was confirmed on amino-acid analysis of the peptides (Table 1) which indicated a replacement of the sole valine, the N-terminal residue of  $\beta$ Tp IX, by alanine as shown in Table 2. Additional proof was obtained by determination of the N-terminal of the  $\beta$ Tp IX peptide using the micro dansyl chloride method of Gray and Hartley<sup>11</sup>. This showed that the upper normal peptide has valine as its N-terminal residue and the lower has alanine. Analysis of all the other peptides of the  $\beta$  chain indicated that they have the expected amino-acid composition. It was therefore concluded that the structural

Fig. 4. Fingerprint of the amino-ethylated  $\beta$  chain of haemoglobin Sydney with some  $\beta$  chain of haemoglobin A present. (For details see text.)

abnormality in haemoglobin Sydney was the replacement of valine at position 67 (E11) of the  $\beta$  chain by alanine. E11 is occupied by valine in all known globins with the exception of the lamprey when isoleucine, which is of similar dimension, is found.

A feature of the unstable haemoglobins as a group is their failure to show the same electrophoretic differences from haemoglobin A as the other abnormal haemoglobins. The explanation of this seems to be that they mostly have, like haemoglobin Sydney, amino-acid abnormalities which do not in themselves alter the charge of the haemoglobin from that of haemoglobin A. This is true of haemoglobin Köln<sup>5</sup> and haemoglobin Genova<sup>7</sup> and is also true of the six other unstable haemoglobins that are at present under investigation in Cambridge. Electrophoresis of the globin from these in 6.5 molar urea shows no change in charge from that of globin A. From the genetic code<sup>12</sup> it is to be expected that there will be about twice as many mutations which do not involve a charge change as those that do. Even so, it is surprising to see the preponderance of non-charge changes in the unstable haemoglobins. Examination of the globin molecule as proposed by Perutz, Kendrew and Watson<sup>13</sup> provides an explanation. They point out that the principal forces responsible for the configuration and stability of the globin molecule are the hydrophobic bonds formed by internally sited residues that are invariably non-polar. The replacement of one of these non-polar residues by a charged residue would almost certainly result in a totally non-viable molecule<sup>13</sup>. The replacement of internal hydrophobic residues by other non-polar residues of different dimensions could result, however, in a degree of instability not totally incompatible with survival of the molecule. This is the defect demonstrated in haemoglobin Köln where a methionine replaces the smaller valine at FG5 and again in haemoglobin Sydney when the valine at E11 which bonds with the porphyrin ring is replaced by the smaller alanine.

There will, of course, be exceptions to this rule; the replacement of the distal histidine E7 by arginine to give the unstable haemoglobin Zürich is one. Another exception is haemoglobin M Milwaukee in which the same residue as in haemoglobin Sydney, valine E11, is replaced by glutamic acid. In this case the acidic group can bond to the haem iron, and the  $\gamma$  carbon of the glutamic acid side chain can form the same hydrophobic bond with the porphyrin ring which is formed by valine, thus giving stability to the molecule. From our experience and from theoretical considerations, however, it seems likely that the majority of point mutations giving rise to instability of the haemoglobin molecule will be replace-

## Fibrinolytic Response to Moderate, Exhaustive and Prolonged Exercise in Normal Subjects

PREVIOUS studies of the fibrinolytic response to a short period of moderate exercise and intravenous adrenaline in a group of healthy subjects have revealed a small subgroup whose response to these procedures appears to be impaired<sup>1,2</sup>. It was suggested that these poor responders could be at risk to conditions such as atherosclerosis and thrombosis and irreversible shock in which defective fibrinolysis has been suggested to be an important aetiological factor<sup>3,4</sup>. It seemed possible, however, that our definition of a poor responder was too restrictive, for the fibrinolytic stimulants were submaximal and of relatively short duration. The following communication describes a series of experiments in which healthy subjects aged between 22 and 50 yr (mean, 36 yr) were subjected to moderate, exhaustive and prolonged exercise procedures at intervals of more than a week.

The fibrinolytic assays for this study were identical to those described previously<sup>1</sup> with the exception that the end points for the time of euglobulin clot lysis were recorded on an automatic clot lysis recorder<sup>5</sup>. The

moderate exercise procedure consisted of an 8 min walk on a treadmill moving at 3.4 m.p.h. with 5° elevation. The exhaustive exercise procedure involved walking on a treadmill at 10° elevation for 3 min at 3.4 m.p.h., followed by 3 min at 3.7 m.p.h., then 1 min at 4.0 m.p.h. and if possible a further minute at 4.2 m.p.h. The prolonged exercise procedure was a 3 h treadmill walk on the flat at 4.0 m.p.h. The exercises were performed in a room at 19°–20° C where all subjects were required to rest, lying down, for 30 min before exercising. Fluid in the form of orange juice was provided freely throughout the prolonged exercise procedure.

Samples of blood were obtained from the cubital vein by separate venipuncture with the minimum of venous occlusion. The percentage fibrinolytic response was calculated as  $\frac{A-B}{A} \times 100$  where *A* and *B* represented the

pre- and post-exercise euglobulin lysis times, respectively.

The results of the moderate and exhaustive exercise studies in six subjects are summarized in Table 1. All subjects spontaneously terminated the exhaustive exercise during the last 10 sec of the final minute when the mean pulse rate had risen to 198/min. The findings would indicate that poor fibrinolytic responders to a moderate exercise procedure could not correct this defect when submitted to a short exhaustive exercise procedure and that submaximal exercise procedures could be used for future epidemiological studies.

Table 1. PERCENTAGE FIBRINOLYTIC RESPONSE TO A MODERATE AND EXHAUSTIVE EXERCISE PROCEDURE IN SIX HEALTHY SUBJECTS

Subject	Percentage response (ELT) to moderate exercise	Percentage response (ELT) to exhaustive exercise
G.W.	42	82
J. C.	45	82
G. McK.	50	89
W. G.	12	46
M. A.	10	43
B. G.	10	53

ELT, euglobulin lysis time.

The prolonged exercise was performed by eleven volunteers and the results, along with their moderate exercise grading, are shown in Table 2. Fig. 1 illustrates the times for euglobulin lysis throughout the exercise period. The results would indicate that the fibrinolytic activity increased during the exercise but plateaued at about 2 h in all but one of the subjects. (Subject I. F. exercised for a further 2 h during which time there was no further change in his times of euglobulin lysis.) There were no significant differences in the contents of euglobulin plasminogen, fibrinogen and plasma urokinase inhibitor before and after the exercise in the subjects examined (Table 3).

The demonstration of a plateaued fibrinolysis at the 2 h interval confirms the observations of Ogston and Fullerton<sup>6</sup>, but this finding was not applicable to one of our subjects (M. A.) and could not be explained by the very low level of pre-exercise fibrinolysis, because comparison with another subject (G. McK.), whose pre-exercise time for euglobulin lysis was similar, showed the marked difference between these two subjects (Fig. 2). It is of interest to

Table 2. PLASMINOGEN ACTIVATOR RESPONSE TO A PROLONGED TREADMILL EXERCISE PROCEDURE

ELT, euglobulin lysis time.

Table 3. CHANGES IN EUGLOBULIN FIBRINOGEN AND PLASMINOGEN AND PLASMA UROKINASE INHIBITOR BEFORE AND AFTER A PROLONGED TREADMILL EXERCISE PROCEDURE

Subject	Euglobulin fibrinogen (mg per cent)		Euglobulin plasminogen (c.u./ml.)		Fibrin plate inhibitor assay (area in mm <sup>2</sup> )			
	Before	3 h	Before	3 h	Before 3 h			
					1	1	1	1
D. M.	250	252	4.55	4.51	100	132	81	110
G. McK.	194	187	3.01	3.04	144	225	144	225
I. W.	320	301	3.25	3.31	100	175	100	195
I. F.	182	191	2.10	2.40	—	—	—	—
D. F.	272	282	3.27	3.10	—	—	—	—

note that subject M. A. was a poor responder to both the moderate and exhaustive exercise procedures. Subject B. G., however, was also a poor responder to the moderate and exhaustive exercises but responded to the prolonged exercise in a manner which was similar to the normal group. This would suggest that there are two types of poor fibrinolytic responders: those whose mechanisms are impaired to short duration stimulation only and those who are resistant to both long and short term stimulation. This differentiation may prove to be relevant when further thought is given to the physio-pathological significance of the poor fibrinolytic responder.

Fig. 1. The time of euglobulin lysis before and during a period of prolonged exercise. The continuous line represents the mean, with the range, of ten subjects. The interrupted line represents the response of subject M.A. (see text).

Fig. 2. A comparison of the fibrinolytic response to the prolonged exercise procedure between two subjects, G. McK. (●) and M.A. (○), whose pre-exercise times of euglobulin lysis were similar.

The finding that, despite a wide range in the times of resting euglobulin lysis (77–780 min) in the remaining ten subjects, the final time of euglobulin lysis plateaued at a mean of 49 min with a standard deviation of 12 min was unexpected and of considerable interest. This observation suggests that comparison of the times of euglobulin lysis between normal individuals is valid and that the differences in the resting concentrations of plasminogen activator between individuals represent normal variations in the homeostatic mechanisms controlling the complex system of *in vivo* thrombolysis. It further suggests that the concentration of circulating plasminogen activator, at least in the unstimulated state, may not represent the concentration of active fibrinolysis, because other influential factors, including the mechanisms of fibrinolytic inhibition, may prove to be of great importance<sup>7</sup>. In situations of stress, however, when rapid dynamic changes of fibrinolysis are required, the ability of the individual to augment the concentration of plasminogen activator could be the single most important factor in maintaining homeostasis.

We wish to thank the volunteers; Mr A. G. E. Allan for invaluable technical assistance; Dr R. A. Cumming, Director of the South-East Scotland Regional Blood Transfusion Centre, for providing the laboratory facilities, and Professor K. W. Donald for the treadmill facilities. ### Combined Action of Phytohaemagglutinin and RNA on Lymphocytes from Patients with Hodgkin's Disease

It is well known that patients with Hodgkin's disease may exhibit a gradually diminishing delayed hypersensitivity<sup>1</sup>. *In vitro* experiments have also revealed a diminished response by lymphocytes from such patients to the blastogenic stimulus of phytohaemagglutinin (PHA)<sup>2-5</sup>, tuberculin and other antigens<sup>6</sup>. We have found that these phenomena are closely related. Diminished lymphocyte response to such a stimulus can be shown *in vitro* only with lymphocytes from skin-negative subjects, and when skin hypersensitivity remains unchanged the lymphocyte culture produces a normal percentage of blast cells<sup>7</sup>.

The mechanism responsible for this phenomenon is still not clear. Because an increased synthesis of RNA has been shown to be one of the first metabolic changes in the production of lymphocyte blast cells in the case of normal subjects<sup>8-14</sup>, we decided to investigate the effect of the combined action of PHA and of RNA from normal human lymph tissue on cultures of lymphocytes from patients with Hodgkin's disease.

Blood from seven skin-negative and two skin-positive patients suffering from Hodgkin's disease was used to prepare lymphocyte cultures<sup>6</sup>. RNA was extracted from biopsy specimens of normal human lymph tissue according to the technique developed by Kirby<sup>15</sup> and modified by Ralph and Bellamy<sup>16</sup>. The extraction was carried out in phenol at both 4° C and 60° C (ref. 17). The RNA and PHA were added to the cultures at concentrations of 0.8 mg/c.c. and 4 µg/c.c., respectively.

Table 1. PERCENTAGE OF BLAST CELL PRODUCTION IN LYMPHOCYTE CULTURES FROM SKIN-POSITIVE SUBJECTS WITH HODGKIN'S DISEASE AFTER STIMULATION WITH PHA AND WITH PHA + RNA

Case	PHA	PHA and RNA immediately	PHA followed by RNA after 24 h
1	55	38	43
2	75	67	68

Table 2. PERCENTAGE OF BLAST CELL PRODUCTION IN LYMPHOCYTE CULTURES FROM SKIN-NEGATIVE SUBJECTS WITH HODGKIN'S DISEASE AFTER STIMULATION WITH PHA AND WITH PHA + RNA

Case	PHA	PHA and RNA immediately	PHA followed by RNA after 24 h
1	16	33	46
2	7	6	56
3	20	—	38
4	12	8	46
5	9	18	61
6	3	14	53
7	14	15	57

The method used in the experiments was as follows. The first culture was retained as a control; with the second culture PHA was added immediately; with the third culture both PHA and RNA were immediately added; with the fourth PHA was immediately added and RNA after 24 h. All cultures were discontinued at the 72nd hour.

Our results were as follows. With the skin-positive subjects (Table 1) normal blast production was already under way and the addition of RNA either simultaneously with the PHA or after 24 h effected no changes. The simultaneous addition of PHA and RNA to the lymphocyte cultures from skin-negative patients (Table 2) had no significant effect on the percentage of blast cell production. When RNA was added to the cultures 24 h after PHA had been added, the percentage of blast cell production was decidedly higher than that when only PHA was added and in some cases approached the percentages found in cultures derived from normal subjects (Table 2).

Our previous investigations showed that PHA protects lymphocyte cultures from both normal and skin-negative patients with Hodgkin's disease from irradiation in a similar way<sup>18</sup>. We suggested that with the skin-negative group the early stages of culture after stimulation with PHA are biologically the same as those of the normal group but that in a second stage there is a lack of a factor necessary for the further development of blast cells. Our present experiments suggest it is in fact a quantitative and qualitative lack of a particular type of RNA which displays its activity at 24 h and thus carries on and ensures the completion of the normally initiated biological cycle. Our experience suggests that the addition of lymphoreticular RNA to cultures obtained from skin-negative patients with Hodgkin's disease serves to stimulate the transformation of blast cells.

We believe it to be unlikely that after stimulation with RNA and PHA the production of blast cells resulted from the presence of RNA antigen complexes in our RNA preparation. In fact, in our control cultures there was no significant increase in the production of blast cells in either normal or Hodgkin subjects<sup>19,20</sup>. A low level of production of blast cells has frequently been found in lymphocyte cultures from subjects with chronic lymphocytic leukaemia<sup>21-23</sup>. During the course of experiments which are still in progress we have found a considerable increase in the percentage of blast cell production in such cases after the same type of RNA has been added; however, the techniques used were somewhat different to those reported here<sup>20</sup>.

Further research is now being undertaken to determine which fraction of the RNA we used is responsible for the activation of blastogenesis in the lymphocyte cultures from patients with Hodgkin's disease.

### Immunological Similarity of Horse, Donkey and Mule Haemoglobins

HORSE haemoglobin has been shown to consist of two components with different electrophoretic mobilities at pH 8.6 (refs. 1 and 2). In the donkey a single haemoglobin is present, corresponding in mobility to the "slow" horse component. In the mule and hinny, two fractions can be distinguished by electrophoresis, with mobilities corresponding to those of horse haemoglobin. Mixtures of horse and donkey haemoglobins behave electrophoretically like mule haemoglobin<sup>2,3</sup>.

An attempt is reported here to distinguish between these haemoglobins by immunological methods.

Whole haemoglobin solutions were prepared by the method of Jonxis and Huisman<sup>4</sup>, with final clarification by centrifugation at 15,000g for 1 h. They were converted to cyanmethaemoglobin, adjusted to 10 g/100 ml., and stored frozen at -25° C. Preparations of the "fast" and "slow" horse and mule components were obtained by electrophoresis of haemoglobin in *tris* buffer<sup>5</sup> at pH 8.6 in agar gel, followed by elution of the separate bands in phosphate-buffered saline at pH 7.0. The eluates were concentrated to about 1.5 g/100 ml. by dialysis against 'Carbowax'<sup>6</sup>, and subsequently diluted as required. Immune precipitating sera against whole horse haemoglobin were prepared in two rabbits by intramuscular injection of haemoglobin solutions mixed with Freund's adjuvant. A primary course of four injections, each of 50 mg of haemoglobin, was given at weekly intervals. After a rest period of 4 months a second similar course was given.

The sera were tested against haemoglobin solutions by double diffusion in agar, by immunoelectrophoresis, and in precipitation reactions by the method of Dean and Webb<sup>7</sup>.

In gel diffusion experiments, both sera, when tested undiluted against horse, donkey and mule haemoglobins, showed precipitation which was optimum at an antigen concentration of 80 µg/ml. No precipitation occurred with sera obtained before immunization. When donkey haemoglobin and the "fast" and "slow" components of horse and mule haemoglobins were compared on one plate at the optimum concentration, a single precipitin line was obtained, showing the immunological similarity of all the antigens. Fig. 1 shows the result with serum 1.

A similar result was obtained with serum 2. No precipitation was obtained with human haemoglobin A. Slight diffuse precipitation occurred when anti-horse haemoglobin serum was tested against horse serum, but disappeared when the latter was diluted beyond 1 in 4.

Immunoelectrophoresis confirmed that the sera were reacting with haemoglobin. Horse haemoglobin components separated by electrophoresis in agar were allowed to diffuse towards two anti-horse haemoglobin sera (Fig. 2). A continuous bow-shaped precipitin line developed, corresponding to the "fast" and "slow" haemoglobin components. After washing, this band could be stained with lissamine green, and also with the *o*-dianisidine reagent of Owen, Silberman and Got<sup>3</sup>, because of the peroxidase activity of the haemoglobin in the precipitate. Another weaker precipitin line occurred nearer the origin, presumably from a reaction with non-haemoglobin protein, because it could be stained with lissamine green but not with dianisidine.

Table 1. OPTIMUM HAEMOGLOBIN CONCENTRATIONS FLOCCULATING WITH A 1/10 DILUTION OF ANTI-HORSE HAEMOGLOBIN SERUM

Antigen	Concentration of antigen ( $\mu\text{g}/\text{ml.}$ )	Flocculation time (min)
Whole horse Hb	56.6	10.5
"Fast" horse Hb	50.5-56.6	12.5
"Slow" horse Hb	50.5-56.6	12.5
Donkey Hb	56.6	13.5
Whole mule Hb	50.5-56.6	10.5
"Fast" mule Hb	50.5-56.6	12
"Slow" mule Hb	50.5-56.6	10.5

Precipitation reactions in tubes were carried out with serum 1, using the constant antibody procedure of Dean and Webb<sup>7</sup>. A preliminary rough titration with doubling dilutions of antigen from 5,120 to 5  $\mu\text{g}/\text{ml.}$  was followed by an accurate titration using antigen diluted in 0.05 log steps from 80 to 35.7  $\mu\text{g}/\text{ml.}$ , standardized in a spectrophotometer. Anti-horse haemoglobin serum at one in ten dilution reacted optimally with an equal volume of horse haemoglobin at 56.6  $\mu\text{g}/\text{ml.}$ , with a flocculation time of 10.5 min. The optimum concentrations of donkey haemoglobin and the "fast" and "slow" components of horse and mule haemoglobins are shown in Table 1. Where the optimum lay between two tubes, the antigen concentrations of both tubes are given. Further evidence of the immunological similarity of the haemoglobins is shown by the fact that the optimum ratio was the same for them all. After precipitation had proceeded to completion (2 h at 37° C, 24 h at 4° C), the supernatants in the zone of optimum proportions were colourless and the precipitates faintly pink. No antigen could be detected in these

Fig. 1. Double diffusion in agar. Centre well: anti-horse haemoglobin serum, undiluted. Outer wells: FH, "fast" horse haemoglobin component; SH, "slow" horse haemoglobin component; H, whole horse haemoglobin; SM, "slow" mule haemoglobin component; FM, "fast" mule haemoglobin component; D, donkey haemoglobin. The concentration of all haemoglobins was 80  $\mu\text{g}/\text{ml.}$

Fig. 2. Immunoelectrophoresis of horse haemoglobin. Above: horse haemoglobin components separated by electrophoresis in Tris buffer at pH 8.6 in agar (contact print on sensitive paper). Below: after diffusion towards two different anti-horse haemoglobin sera. Washed, then stained with lissamine green.

supernatants by precipitin ring tests with immune serum, although the original haemoglobin solutions reacted well.

Spectrophotometric examination showed that at the optimum ratio no haemoglobin pigment was detectable in the supernatant but that all the pigment was released when the washed precipitate was redissolved in one-tenth normal sodium hydroxide.

Kilmartin and Clegg<sup>9</sup> have recently shown that the electrophoretically "fast" component of horse haemoglobin differs from the "slow" component in possessing glutamine instead of lysine at position 60 in the  $\alpha$ -polypeptide chain. In addition each  $\alpha$ -chain may have either tyrosine or phenylalanine at position 24, thus allowing four possible types of  $\alpha$ -chain. The composition of the  $\beta$ -chain is the same in both components. In the single haemoglobin of the donkey, the  $\alpha$ -chain has lysine at position 60, phenylalanine at 24, and differs from horse  $\alpha$ -chains in having asparagine instead of histidine at position 20. The mechanism of the heterogeneity of horse  $\alpha$ -chains is unknown, but if the mule inherits one  $\alpha$ -chain gene from each parent then five types of  $\alpha$ -chain might be possible.

Our experiments show that horse, donkey and mule haemoglobins are immunologically similar, and that the differences between them, now known to involve substitutions of only one or two amino-acids, cannot be detected by the serological methods described in this communication.

## IMMUNOLOGY

## Large Amounts of Non-agglutinating Anti-erythrocyte IgG in Primary Antisera

It is generally accepted that IgM are synthesized before IgG antibodies. This sequence could depend on the characteristics of the antigen, its route of administration, the dosage used, and the animal species studied<sup>1</sup>. There is some doubt as to whether IgM antibodies are predominant in some early primary antibody responses<sup>2-4</sup>. This question arises in part from the fact that haemagglutination is more sensitive for detecting IgM than IgG antibodies<sup>2,5,6</sup>; and in part from the observation that haemolytically inefficient IgG antibodies are undetected in the Jerne plaque technique<sup>7</sup> unless indirect procedures are used<sup>8,9</sup>. Indeed, sera obtained soon after injection of proteins may have more IgG than IgM precipitins<sup>10-12</sup>. Thus there is a need for re-evaluation of the magnitude of the IgG response in the early stages of antibody production. Evidence is presented that sera from chickens immunized with sheep red blood cells (SRBC) contain more IgG than IgM antibody 6 days after injection.

Primary immune responses were induced in male and female adult White Leghorn chickens by intravenous injection of suspensions of washed sheep red blood cells. Individual sera and fractions were heated at 56° C for 30 min, and haemagglutination titres were determined by two-fold dilutions and addition of 0.1 ml. of 2 per cent red blood cells. Titres are expressed as the reciprocals of the dilutions.

Antibodies were present within 3 days of immunization in all birds which had received either 1 per cent, 5 per cent or 10 per cent red blood cells. Maximum titres were attained 6 days after primary injection. Fractionation by gel filtration in 'Sephadex G-200' (ref. 13) and by diethylaminoethyl-cellulose chromatography<sup>14</sup> indicated that individual primary sera contained mostly IgM agglutinins. This was confirmed by sucrose-gradient ultracentrifugation<sup>14</sup> and by treatment of sera with 0.1 molar 2-mercaptoethanol. Thus, based on haemagglutination, and on fractionation procedures commonly used for delineation of IgG and IgM antibodies, these responses resembled in some respects the anti-bovine serum albumin responses of chickens<sup>14</sup>, that is, little or no haemagglutinating IgG antibody is demonstrated in the early primary response. The following experiments showed that large amounts of IgG non-agglutinating antibody were present.

To elute antibodies from agglutinated cells, 4 ml. of a 6 day primary antiserum was reacted with 4 drops of packed formalized cells<sup>15</sup>/ml. of serum for 40 min at 37° C. The agglutinated cells were washed three times with cold borate buffer (pH 8.2  $\Gamma/2=0.16$ ) by centrifugation, and finally suspended in 1.5 ml. of buffer. Elution was carried out twice at 56° C for 5 min each. Analysis of the eluates by immunoelectrophoresis showed only IgG and albumin arcs. Albumin also may be a co-complexing contaminant in the precipitin reaction, as shown by Orlans *et al.*<sup>16</sup>. The agglutinins (titre, 320) in the eluates were completely inactivated by 0.1 molar mercaptoethanol in conditions known to completely inactivate IgM but not IgG antibodies<sup>17</sup>.

For anti-globulin tests (Coombs's reaction), IgG was isolated by gel filtration from a 6 day primary antiserum (titre, 10,240). A 1.0 per cent solution contained no IgM shown by gel diffusion analysis. After titration of the solution by haemagglutination, the cells were washed three times with borate buffer by centrifugation and resuspended in 0.5 ml. of buffer. To duplicate sets was added either 0.04 ml. or 0.08 ml. of heat-inactivated and absorbed rabbit anti-chicken globulin antiserum. Identical tests were performed with a 1.0 per cent solution of normal IgG. The results, summarized in Table 1, show that before and after addition of rabbit antiserum the titres of the IgG fraction were less than 5 and 640, respectively. Cells

treated with normal IgG failed to absorb detectable IgG. For additional tests to show the presence of non-agglutinating antibodies in this preparation, sheep red blood cells were treated with bromelain<sup>18</sup> and with ficin<sup>19</sup>, procedures used to demonstrate non-agglutinating antibodies for human erythrocytes. Both enzymes increased the titres (Table 1).

To determine the approximate number of IgG and IgM antibody molecules absorbed to the red blood cells, IgG and IgM globulins were isolated from a 6 day primary antiserum by repeated precipitation with sodium sulphate (ref. 13), followed by repeated cycles of gel filtration in 'Sephadex G-200'. The preparations were iodinated<sup>20</sup> with iodine-125. The specific activity of the IgM preparation was 1.38 relative to the IgG preparation, a value in close agreement with that reported by Greenbury *et al.*<sup>5</sup> for iodination of rabbit IgG and IgM. One millilitre each of the IgG (0.280 mg) and the IgM (0.190) preparations were reacted with  $1.25 \times 10^9$  sheep red blood cells at room temperature for 30 min. The cells were recovered by centrifugation, and to the supernates were added the same quantities of red blood cells: a total of  $2.50 \times 10^9$  cells were used to absorb the fractions. The cell suspensions were washed three times with 0.5 per cent bovine serum albumin in borate; the radioactivities of the cells and supernatant fluids were counted after each washing. The final radioactivity count of the cells of the original reaction tube was added to the count of the cells from the second absorption step. The sum of these values was taken as the total absorbable antibody. The experiment was performed in duplicate, using the same globulin preparations but at different times. To control for non-specific absorption, purified normal chicken IgG was labelled with iodine-125 and reacted with sheep red cells as previously described. The molecular weight of chicken IgG was taken as 206,000 (ref. 21), and the molecular weight of IgM was assumed to be 900,000 (refs. 22 and 23). Approximately 1 per cent of the labelled normal IgG was absorbed to cells. As shown in Table 2, when  $8.16 \times 10^{14}$  molecules of IgG were reacted with  $2.50 \times 10^9$  cells, approximately  $2.5 \times 10^{14}$  molecules of IgG antibody were bound, or about  $1 \times 10^5$  molecules in each cell. About 31 per cent of the molecules in this preparation were therefore non-agglutinating anti-sheep red blood cell antibodies. This represents about  $9.02 \times 10^{14}$  anti-sheep red blood cell molecules absorbed/mg of IgG. Of the  $1.29 \times 10^{14}$  molecules of IgM, approximately  $4.23 \times 10^{13}$ , or 32 per cent, were absorbed; this represents about  $1.70 \times 10^{14}$  molecules of IgM antibodies absorbed/mg of protein. Based on these preparations, there were about four molecules of IgG antibody to one molecule of IgM antibody. Greenbury *et al.*<sup>5</sup> reported that at saturation each human group A<sub>1</sub> red blood cell was capable of absorbing  $8.3 \times 10^5$  molecules of rabbit IgG antibody, or  $1.7 \times 10^5$  molecules of IgM antibody. The A<sub>1</sub> cells take up only about one fifth the number of IgM molecules compared with IgG. Although we did not determine whether the

Table 2. MOLECULES OF RADIOIODINATED CHICKEN IgG AND IgM ANTIBODIES ABSORBED TO  $2.50 \times 10^9$  SHEEP RED BLOOD CELLS

Antibody preparation*	Titre	Added to SRBC		Absorbed by SRBC	
		(mg)	No. of molecules (cpm)	(cpm)	Molecules/mg of protein
IgG	< 5	0.280	$8.16 \times 10^{14}$	10,777	Mean: 3,305
IgM	160	0.190	$1.29 \times 10^{14}$	9,915	Mean: 3,250

SRBC, sheep red blood cells.

\* Fractions obtained by gel filtration of a 6-day primary anti-SRBC serum. Approximately 1 per cent of radioiodinated normal chicken IgG was absorbed.

sheep red blood cells were saturated with antibody, the values of  $1 \times 10^5$  molecules of IgG and  $1.7 \times 10^4$  molecules of IgM/cell were of the same orders of magnitude as those reported by Greenbury *et al.*<sup>5</sup>.

We have found that 3–4 days after immunization with either bovine serum albumin or haemocyanin many chicken antisera contain only IgM antibodies as detected by radioimmuno-electrophoresis, and that by day 4 or 5 the IgG antibodies predominate—indicating that the period of time in which only IgM antibodies were demonstrable was short—one day (unpublished work). Whether sheep red blood cell IgM antibodies appear in the serum before IgG still remains to be determined. Nevertheless, it is obvious from the present investigation that studies on the temporal synthesis of anti-erythrocyte antibodies in chickens, and most likely in other animal species, should include consideration of the serum non-agglutinating IgG antibodies, which represent as many molecules as do IgM antibody molecules 6 days after immunization.

### Early Splenectomy and Survival of Inbred Mice

THE spleen is known to function in lymphopoiesis<sup>1–3</sup>, phagocytosis<sup>4,5</sup>, and immunogenesis<sup>6–8</sup>, but these functions are not essential to normal survival or health when the spleen is removed during adult life<sup>9–11</sup>. The spleen appeared in the primitive fishes and has persisted in much the same morphological state in all vertebrates which have evolved since<sup>12–14</sup>. Such phylogenetic constancy implies survival advantage, but the basis of this advantage remains enigmatic.

The syndrome of congenital cardiac disease associated with failure of the spleen to develop is rare, but has been repeatedly associated with overwhelming infection in early life<sup>15,16</sup>. King and Schumacher<sup>17</sup> reported that children with haemolytic anaemia subjected early to splenectomy are prone to develop overwhelming infection. It has been established that splenectomy early in life in children with a variety of haematological diseases<sup>18–22</sup>,

but not necessarily in normal children, causes a great risk of infection with extracellular pyogenic bacterial pathogens, particularly pneumococci<sup>23–31</sup>. These observations suggest that the most important part played by the spleen is in ontogenetic development. Neonatal splenectomy enhances susceptibility to pneumococcal infection in mice<sup>32</sup>. These relationships suggested to Ellis and Smith<sup>33</sup> that the dual phagocytic and immunogenetic role of the spleen is especially important in the early period of exposure to extrauterine life.

Globerson<sup>34</sup> presented evidence from *in vitro* studies that interaction of thymus, spleen, and bone marrow fragments may be essential to the development of certain forms of immunological capacity. Removal of the thymus in the immediate neonatal period in rabbits<sup>35,36</sup> and rodents<sup>37–41</sup> has provided clues to the importance of this organ in developmental biology, and so we decided to look again at the possible significance of the spleen from the same ontogenetic point of view. It is the purpose of this report to describe the effects of splenic extirpation at different ages in the life of inbred mice on survival of the animals.

It was found that neonatal splenectomy, like neonatal thymectomy, produces in mice a high mortality rate during the first 6 weeks of life. Like thymectomy, splenectomy at birth produces runting and wasting disease and interferes with the normal development of the lymphoid system.

C3H/BI mice were subjected to splenectomy in the immediate neonatal period (less than 15 h old) or when 2 or 4 weeks of age. For comparison, mice were thymectomized during the first 15 h of life or 2 and 4 weeks after birth. All mice were kept in air conditioned quarters and nursed by their own mothers until they were 4 weeks old. After weaning the animals were fed 'Purina' fox chow and water *ad libitum*.

The mice were checked every day during the first 3 weeks and at least three or four times a week thereafter. Deaths were recorded and the size and health of the animals noted and recorded.

In one experiment 227 mice were splenectomized during the first 15 h of life, eighty at 2 weeks old, and seventy-five at 4 weeks old. A hundred and nine mice were subjected to neonatal thymectomy, seventy-five to thymectomy at 2 weeks and seventy-two to thymectomy when 4 weeks old.

The survival of the mice of the several groups up to 6 weeks of age is recorded in Table 1. In mice of this strain raised in the conditions existing in these laboratories both thymus and spleen are organs essential to survival. Removal of either organ in the immediate neonatal period had a much more profound effect on survival than did removal at either 2 or 4 weeks. 153 of the 227 mice subjected to splenectomy in the neonatal period had already died by 6 weeks. Most of these deaths occurred between the third and fourth weeks of life. By contrast only twelve out of eighty, or 15 per cent of mice splenectomized at 2 weeks, had died by the sixth week and only five out of seventy-five mice splenectomized at 4 weeks were dead at this age. Further, we observed that mice splenectomized at either 2 or 4 weeks, and kept much longer in our laboratory, very rarely died between the sixth and twelfth week of life.

Mice splenectomized at birth often showed a runting and wasting syndrome similar to that associated with neonatal thymectomy. This process seemed to begin between the twelfth and sixteenth day of life and regularly to have its onset earlier than did the runting and wasting syndrome

Table 1. EFFECT OF SPLENECTOMY AND THYMECTOMY ON SURVIVAL OF C3H MICE

	Splenectomy			Thymectomy		
	New-born	2 weeks	4 weeks	New-born	2 weeks	4 weeks
No. mice operated	227	80	75	109	75	72
Survival to 6 weeks	74	68	70	54	61	64
Dead by 6 weeks	153	12	5	45	14	3
Mortality (per cent)	67.4	15	6.7	41.3	18.7	4.2

observed in neonatally thymectomized mice of the same genetic composition raised in this laboratory. The runted animals seemed always to have loose stools associated with failure of normal growth rate and then later with actual weight loss.

The table shows by comparison that neonatally thymectomized *C3H/Bi* mice had experienced 41 per cent mortality rate at 6 weeks and 16 per cent and 5 per cent mortality rate by 6 weeks when thymectomized at 2 and 4 weeks of age respectively. The latter observations agree with extensive previous experience in this laboratory with neonatally thymectomized *C3H/Bi* mice and seem representative of the effects of early and later thymectomy in the existing conditions.

Haematological studies<sup>41</sup> showed that neonatal splenectomy had effects very different from those observed when splenectomy was carried out at either 2 or 4 weeks of age. We found that neonatal splenectomy greatly inhibited the development of a full complement of circulating lymphocytes during the first weeks of life. This was as pronounced as the effect of neonatal thymectomy on the development of this population of cells. Splenectomy at 2 and 4 weeks, like thymectomy at these ages, had a much less profound effect on the development of the population of lymphoid cells in blood and tissues than did either thymectomy or splenectomy carried out in later life.

These observations, which are being extensively developed, have suggested that, as with the thymus, it may be most incisive to investigate the advantage to survival of the spleen in mammalian biology by considering the function of this organ in the ontogenetic development of the haematopoietic tissues.

## Suppression of Graft versus Host Reaction by Mitomycin C

At present there is no adequate therapy for human diseases of immunological deficiency. Immunological reconstitution of children suffering from congenital thymic dysplasia has been attempted using allogeneic lymphoid tissues from pre- or postnatal donors, but these efforts remained unsuccessful<sup>1,2</sup>, or were followed by a fatal reaction of the graft against the host<sup>3</sup>.

In animals with experimental diseases of immunological deficiency, reconstitution has been achieved by transplantation of syngeneic thymus, spleen or lymph node cells<sup>4,5</sup>; injection of allogeneic lymphocytes, however, is usually followed by reaction of the graft against the host<sup>6</sup>.

The graft versus host disease following injection of parental strain spleen cells into *F1* hybrid recipient mice can be modified by immunosuppressive therapy of the host<sup>7-9</sup>, but in immunologically deficient states treatment of the host with these drugs would depress resistance to infection even further.

As a first step in an attempt to restore immunologically deficient animals, and even humans with allogeneic cells, we decided to assess the effect of drugs on donor cells in parent versus *F1* hybrid homologous disease in mice. We chose mitomycin *C* because this drug inhibits cell division, but leaves some immunological functions of the cell intact<sup>10-12</sup>. Our results show that mitomycin *C* in appropriate concentrations prevents graft versus host disease.

A strain and (*A* × *C57BL/1*) *F1* hybrid mice were used. Spleen lymphocytes from adult *A* donors were injected into 7-9 day old (*A* × *C57BL/1*) *F1* hybrids, and the graft versus host assay of Simonsen<sup>13</sup> used. Each litter of six or more *F1* hybrid animals was divided into groups, and members of each group injected with either syngeneic *F1* hybrid spleen cells, untreated *A* strain spleen cells, or *A* strain spleen cells treated with various doses of mitomycin-*C*. Spleens from donor animals were made into cell suspensions in Eagle's minimum essential medium by a method described earlier<sup>6</sup>. About 10<sup>7</sup> lymphocytes were injected intraperitoneally into each 7-9 day old recipient in a volume of approximately 0.1-0.2 ml. Injected animals were killed 8 days later and spleen and body weights determined. The "spleen index" was calculated by dividing the spleen weight/10 g of body weight of each of the experimental animals by the mean spleen weight obtained in the group injected with *F1* hybrid spleen cells. Spleen indices greater than 1.30 are considered to indicate significant graft versus host reactivity on the part of the injected cells.

Treatment with mitomycin *C* was performed by incubation with the drug for 20 min at 37° C at a concentration of 100, 10 or 5 µg of mitomycin *C*/ml. of cell suspension. After incubation the cells were washed twice to remove

the drug. Control *A* strain spleen cells and *F1* hybrid cells were simultaneously treated in an identical manner but not exposed to mitomycin *C*. Cell viability before injection (as determined by trypan blue exclusion) was greater than 90 per cent and was not altered by treatment with mitomycin *C*.

From Fig. 1 it is evident that *A* strain spleen lymphocytes consistently caused significant splenomegaly in (*A* × *C57/BL/1*) *F1* hybrids, and that treatment of these cells with mitomycin *C* impaired this ability. One hundred micrograms of mitomycin *C*/ml. of cell suspension abolished the graft versus host reaction completely. In the group of animals injected with *A* strain spleen cells incubated with 10 µg of mitomycin *C*, one animal out of twelve showed significant splenomegaly. In the group injected with spleen cells treated with 5 µg of the drug two animals out of seven showed significant splenomegaly. Thus while mitomycin *C* appears to inhibit graft versus host reactions, this effect is greater when higher doses are used.

Fig. 1. Graft versus host assays of untreated and mitomycin *C* treated *A* strain spleen cells. Each bar represents the spleen index obtained by injection of the *A* strain spleen cells into one (*A* × *C57/BL/1*) *F1* hybrid. Solid and cross-hatched bars represent separate experiments. *Am* 100, *Am* 10, *Am* 5 are cells treated respectively with 100, 10, and 5 µg mitomycin *C*/ml.

From recent studies it appears that mitomycin *C* has an inhibitory effect on DNA replication, probably because of cross-linkage of the DNA strands<sup>10</sup>. There are indications, however, that protein synthesis continues at near normal rates after cells have been incubated with mitomycin *C* for prolonged periods<sup>11</sup>. In addition, Bloom<sup>12</sup> showed that guinea-pig lymphoid cells incubated with 10 µg of mitomycin *C* for 75 min were able to transfer delayed hypersensitivity, and manifested a vigorous uptake of <sup>3</sup>H-uridine and <sup>3</sup>H-valine into RNA and protein respectively.

From the data presented here it is apparent that mitomycin *C* in appropriate amounts prevents graft versus host reactions in mice. Even when minute amounts of the drug are used, this effect is apparent, although less uniform. Incubation with mitomycin *C* does not impair cell viability as judged by trypan blue exclusion.

A crucial question is whether the treated cells remain metabolically active when injected into syngeneic or allogeneic animals and may confer some degree of immunocompetence on the host. Studies now in progress in our laboratory suggest that allogeneic lymphocytes treated with mitomycin *C* do have beneficial effects in neonatally thymectomized, immunologically deficient mice.

## BIOCHEMISTRY

### Effect of Tropomyosin on the Calcium-activated Adenosine Triphosphatase of Actomyosin

It is well known that the Mg<sup>++</sup>-activated ATPase of actomyosin extracted as the complex from muscle, "natural" actomyosin, is inhibited by low concentrations of ethylene dioxybis(ethyleneamino) tetra-acetic acid (EGTA), a property not possessed by actomyosin prepared from separately purified actin and myosin<sup>1</sup>. During a study of the factors responsible for the differences in enzyme behaviour of these two preparations a simple procedure has been developed which enables "natural" actomyosin to be readily converted to so-called "desensitized" actomyosin, the behaviour of which resembles actomyosin prepared from the independently purified actin and myosin in that its Mg<sup>++</sup>-activated ATPase is no longer sensitive to EGTA<sup>2,3</sup>. It was noted that in addition to the difference in sensitivity to EGTA of the two preparations the specific ATPase activity of "natural" actomyosin in the presence of Ca<sup>++</sup> was 30–50 per cent of that of the desensitized actomyosin.

During the process of conversion of the "natural" to the desensitized form of actomyosin the Ca<sup>++</sup>-activated ATPase rose roughly in parallel with the loss of sensitivity to EGTA and was accompanied by the removal of about 10 per cent of the total protein. When this protein fraction was added to desensitized actomyosin its enzymatic properties were in part restored to those of "natural" actomyosin. An extract with similar properties to that extracted during desensitization of "natural" actomyosin can be obtained from whole myofibrils by prolonged extraction with 5 mmolar *tris*-hydrochloric acid (pH 8.6), the so-called "soluble fraction"<sup>2,4</sup>. The study of this myofibrillar fraction and the extract removed during desensitization of "natural" actomyosin has indicated that the factors responsible for the sensitivity of the Mg<sup>++</sup>-activated ATPase of "natural" actomyosin to EGTA (EGTA sensitizing factor)<sup>5</sup> and for inhibiting the Ca<sup>++</sup>-activated ATPase of desensitized actomyosin are not identical.

Although the factor inhibiting the Ca<sup>++</sup>-activated ATPase had the properties of a protein, it was much more resistant to treatment with heat and trypsin and the effect could be demonstrated at much lower concentrations of the "soluble fraction" than were required to restore

EGTA sensitivity to a desensitized actomyosin preparation (Fig. 1). In view of the stability and solubility properties of the factor modifying the  $\text{Ca}^{++}$ -activated ATPase and the fact that one of the main components of the soluble fraction was known from earlier studies<sup>1</sup> to be tropomyosin, it seemed possible that this protein was responsible for the effect.

All the evidence indicated that this is the case, because three times precipitated preparations of tropomyosin<sup>6</sup>, which gave a single peak in the ultracentrifuge in 1 molar potassium chloride at pH 7.6 and 13.0, were very active in reducing the  $\text{Ca}^{++}$ -activated ATPase of desensitized actomyosin. The maximum effect was obtained when myosin and tropomyosin were present in the systems in approximately molar ratios, under which conditions the ATPase was reduced by about 50 per cent (Fig. 2). Purified tropomyosin preparations of the Bailey-type prepared in the presence<sup>7</sup> or absence of thiol reagents were equally active with respect to their effect on the  $\text{Ca}^{++}$ -activated ATPase, although only the latter preparations had strong EGTA sensitizing activity. Further purification of tropomyosin by ethanol-ether treatment<sup>6</sup> did not impair its inhibitory effect on the  $\text{Ca}^{++}$ -activated ATPase. Tropomyosin precipitated by 5 per cent trichloroacetic acid and redissolved at neutral pH retained unchanged the inhibitory action on the actomyosin ATPase. Likewise tropomyosin denatured by 4.2 molar guanidine-hydrogen chloride and then exhaustively dialysed showed no appreciable loss of its inhibitory effect. Under these conditions tropomyosin has been shown to regain up to 80 per cent of its original helicity<sup>8</sup>.

Tropomyosin had no inhibitory effect on the  $\text{Ca}^{++}$ -activated ATPase of myosin, implying a requirement of actin for the effect. Although the inhibition was pronounced at the conditions of assay used it was much reduced at higher ionic strength, disappearing completely at  $\mu = 0.15$  with desensitized actomyosin. The inhibitory effect of tropomyosin was not obtained with the  $\text{Ca}^{++}$ -activated ATPase of natural actomyosin nor with the

Fig. 1. Effect of heat and tryptic digestion on the ability of the "soluble fraction" of myofibrils to inhibit the  $\text{Ca}^{++}$ -activated ATPase and to confer sensitivity to EGTA on the  $\text{Mg}^{++}$ -activated ATPase of desensitized actomyosin. "Soluble fraction" ( $E_{280}^{1\text{cm}} = 3$ ) treated as indicated before addition. 1/50 part by weight of trypsin was used and the digestion stopped by adding twice the amount of soy bean trypsin inhibitor. Digestion carried out in 5 mmolar *tris*-hydrochloric acid, pH 8.6. ●, Untreated; △, 10 min at 100° C; □, trypsin digestion for 30 min at 0° C; ○, trypsin digestion for 30 min at 25° C. Assay conditions: 0.57 mg actomyosin in 2 ml. containing 25 mmolar *tris*-hydrochloric acid, pH 7.6, 2.5 mmolar *tris*-ATP incubated for 5 min at 25° C with (a) 2.5 mmolar calcium chloride, or (b) 2.5 mmolar magnesium chloride plus 1 mmolar EGTA.

Fig. 2. Effect of tropomyosin on the  $\text{Ca}^{++}$ -activated ATPase of desensitized actomyosin. Bailey-type tropomyosin after two isoelectric precipitation cycles added as indicated to 0.37 mg of actomyosin. Assay conditions as for Fig. 1 in presence of 2.5 mmolar calcium chloride.

$\text{Mg}^{++}$ -activated ATPase of desensitized actomyosin. It is therefore different from that obtained with the inhibitory factor on the  $\text{Mg}^{++}$ -activated ATPase of desensitized actomyosin reported earlier<sup>9</sup>.

According to Ebashi and Kodama<sup>10</sup>, the EGTA sensitizing factor complex consists of tropomyosin associated with another protein, troponin. If this is so, and in view of the role of  $\text{Ca}^{++}$  in controlling the  $\text{Mg}^{++}$ -activated ATPase of the myofibril, the effect of tropomyosin described in this communication might represent one aspect of the mechanism of action of the EGTA sensitizing factor complex. Although the EGTA sensitizing and the  $\text{Ca}^{++}$  ATPase inhibitory effects may be different properties of the complex system regulating the actomyosin ATPase, the effects can be independently demonstrated, and whereas the former acts on the  $\text{Mg}^{++}$ -activated ATPase the latter is only apparent in the  $\text{Ca}^{++}$ -activated system. Further, the properties of the factor responsible for the inhibitory effect on the  $\text{Ca}^{++}$ -activated ATPase parallel those of tropomyosin much more closely than do the properties of the EGTA sensitizing factor. Activity resulting from the latter can be easily lost from tropomyosin preparations whereas the effects on the  $\text{Ca}^{++}$ -activated ATPase persist so long as the tropomyosin structure remains intact. Indeed, this latter property, which is the first clearly defined enzyme effect of tropomyosin on actomyosin, appears to be specific enough to be used as a sensitive test for the presence of this protein.

# Potential of Cortisol Induction of Hepatic Tyrosine Transaminase by $\beta$ -Diethylaminoethyl Diphenylpropylacetate

$\beta$ -DIETHYLAMINOETHYL diphenylpropylacetate (*SKF 525A*) has been demonstrated in the rat to inhibit the metabolism of drugs both *in vitro* and *in vivo*<sup>1,2</sup>. We have demonstrated that the conversion of cortisol to a polar metabolite or metabolites by the 9,000*g* supernatant of the male rat liver is inhibited by the addition of *SKF 525A* to the incubation mixture<sup>3</sup>. The similarity between liver enzymes which metabolize drugs and those which hydroxylate steroids<sup>4</sup> suggested the possibility that *SKF 525A* would inhibit the hydroxylation of cortisol *in vivo*. In turn, it was thought that this inhibition could manifest itself in an increase in the biological activity of administered cortisol. The administration of cortisol is known to increase the activity of rat liver tyrosine transaminase<sup>5,6</sup>. The present investigation demonstrates in the male rat a further increase in cortisol induction of tyrosine transaminase by *SKF 525A*.

Table 1. EFFECT OF *SKF 525A* ON THE INDUCTION OF TYROSINE TRANSAMINASE BY CORTISOL IN ADRENALECTOMIZED MALE RATS

Experiment	Treatment	p-Hydroxyphenylpyruvate ( $\mu$ g)
1	Control (4)	55 $\pm$ 7
	<i>SKF 525A</i> (5)	35 $\pm$ 3
	Cortisol (3)	212 $\pm$ 13*
	Cortisol + <i>SKF 525A</i> (3)	276 $\pm$ 9*
2	Control (3)	38 $\pm$ 7
	<i>SKF 525A</i> (2)	45 $\pm$ 9
	Cortisol (4)	158 $\pm$ 30†
	Cortisol + <i>SKF 525A</i> (5)	244 $\pm$ 17†
3	Control (2)	25 $\pm$ 4
	<i>SKF 525A</i> (2)	34 $\pm$ 8
	Cortisol (5)	222 $\pm$ 18†
	Cortisol + <i>SKF 525A</i> (5)	286 $\pm$ 14†

The average and range of weight (g) of animals in the three experiments were for experiment (1) 153 (136–164); for experiment (2) 185 (165–206), and for experiment (3) 140 (123–158). Animals were dosed subcutaneously with cortisol (500  $\mu$ g) in 0.2 ml. of 0.5 per cent carboxymethylcellulose (CMC) or with 0.2 ml. of CMC. One half hour (experiment (1)) or 45 min (experiments (2) and (3)) before and 2.5 h after the injections of cortisol or CMC, the specified animals were intraperitoneally injected with *SKF 525A* (each injection 25 mg/kg body weight). Assays for p-hydroxyphenylpyruvate were conducted according to a procedure<sup>8</sup> described before in which the concentration of the incubation constituents was modified; an incubation volume of 5 ml. of deionized water contained 3.3  $\mu$ moles of L-tyrosine; 50  $\mu$ moles of sodium phosphate buffer, pH 7.5; 0.113  $\mu$ moles of pyridoxal phosphate; 5  $\mu$ moles of sodium diethyldithiocarbamate, and 0.2 ml. of liver 9,000*g* supernatant. Reaction was initiated by the addition of 0.2 ml. of a solution of 12  $\mu$ moles of  $\alpha$ -ketoglutaric acid and was terminated with 0.5 ml. of 50 per cent trichloroacetic acid solution. After centrifugation, 3 ml. samples were assayed for p-hydroxyphenylpyruvate by a modified Briggs method<sup>12</sup>. Values refer to the mean  $\pm$  standard error of the mean of the product (p-hydroxyphenylpyruvate) formed by the supernatant from 67 mg of liver in 10 min of incubation. Numbers in parentheses refer to number of animals.

\*  $P \leq 0.025$  when the treatment with cortisol and *SKF 525A* was compared with cortisol alone.

†  $P \leq 0.05$  comparisons as in previous footnote.

Male albino Wistar strain rats were obtained from Royal Hart Farms and were fed freely on 'Purina' chow and water. Experiments were conducted on intact and adrenalectomized rats (fourth day after adrenalectomy); after adrenalectomy animals were given 1 per cent saline instead of water. On the day of the experiment, cortisol was suspended (2.5 mg/ml.) in 0.5 per cent carboxymethylcellulose aqueous solution with the help of a Potter-Elvehjem glass homogenizer; *SKF 525A* was dissolved in deionized water so that about 0.4 ml. contained the required dose. Animals were injected with the drugs or with an equivalent volume of the vehicle as described in the tables. Six hours after the injection of cortisol animals were killed by decapitation, blood was drained and livers quickly removed and placed on ice. Supernatant from liver centrifuged at 9,000*g* was prepared as previously described<sup>3</sup>. Tyrosine transaminase assays were carried out on 0.2 ml. samples of the 9,000*g* supernatant by a modification of the method of Sereni *et al.*<sup>6</sup> (Table 1).

Subcutaneous administration of cortisol to mature adrenalectomized male rats caused an increase in the activity of hepatic tyrosine transaminase (Table 1).

When both *SKF 525A* and cortisol were injected a greater increase in enzyme activity was observed. The administration of *SKF 525A* alone did not alter enzyme activity.

Table 2 shows that there was an increase in tyrosine transaminase activity after the administration of *SKF 525A* to intact rats. There was a larger increase in activity of the enzyme after the administration of *SKF 525A* than after the administration of cortisol. When both cortisol and *SKF 525A* were given to the same animal, enzyme activity was similar to that observed after the administration of *SKF 525A* alone.

Our previous observations suggest that cortisol metabolism *in vitro* proceeds in a sequence of two steps: reduction of ring A followed by transformation of the reduced metabolite into a more polar (possibly hydroxylated) derivative<sup>3</sup>. (Hydroxylation of C19 steroids reduced at ring A by rat liver microsomes has been proposed by Chamberlain *et al.*<sup>7</sup>.) Only the latter transformation seems to be inhibited by *SKF 525A*. These findings and the demonstration that the hydroxylation of barbiturates is inhibited by *SKF 525A* both *in vivo* and *in vitro*<sup>1,2</sup> suggest that the larger increase in the activity of tyrosine transaminase caused by the administration of both cortisol and *SKF 525A* as compared with the increase in enzyme activity after the administration of cortisol alone may result from interference with the polar pathway of cortisol metabolism.

Further support for this conclusion comes from the observation that an increase in cortisol metabolism in male rats caused by thyroxine is accompanied by a decrease in the induction of tyrosine transaminase by cortisol<sup>8</sup>. There are other possible interpretations for the potentiation of cortisol activity by *SKF 525A*, such as an increase in the sensitivity of a "receptor site" to cortisol action and/or facilitation of the accumulation of cortisol at its site of action. The latter interpretation may derive support from the observation that *SKF 525A* potentiates the action of curarizing agents presumably by increasing their concentration at certain specific receptors<sup>9,10</sup>.

Table 2. EFFECT OF *SKF 525A* AND CORTISOL ON THE INDUCTION OF LIVER TYROSINE TRANSAMINASE IN INTACT MALE RATS

Experiment	Treatment	p-Hydroxyphenylpyruvate ( $\mu$ g)
1	Control (5)	72 $\pm$ 11
	<i>SKF 525A</i> (5)	227 $\pm$ 10
	Cortisol (5)	156 $\pm$ 5
	Cortisol + <i>SKF 525A</i> (5)	233 $\pm$ 10
2	Control (3)	40 $\pm$ 6
	<i>SKF 525A</i> (3)	173 $\pm$ 18

In experiment (1) the average animal weight was 180 g and in experiment (2) it was 160 g. Animals were dosed subcutaneously with 1 mg of cortisol in 0.2 ml. of 0.5 per cent carboxymethylcellulose (CMC) or with 0.2 ml. of CMC. Injections of *SKF 525A* and other details are described in Table 1; time sequence of injections as in Table 1, experiment (1). Assays were conducted as described in Table 1. Values refer to mean  $\pm$  standard error of the mean of the product formed by the supernatant from 67 mg of liver in 10 min of incubation. Numbers in parentheses refer to number of animals.

The marked increase in tyrosine transaminase after the administration of *SKF 525A* to intact rats (Table 2) and the lack of effect by this compound in adrenalectomized animals (Table 1) suggests that in the intact animals the effect of *SKF 525A* is mediated through stress. The observation that subjecting mature rats to stress (shaking) does not increase the activity of tyrosine transaminase<sup>11</sup>, however, casts doubts on this interpretation. Obviously, it is possible that in intact animals *SKF 525A* merely potentiates the activity of endogenously produced corticoids in a manner proposed for the potentiation of cortisol action by *SKF 525A* in adrenalectomized animals.

The observation by Magus and Fouts<sup>12</sup> that *SKF 525A* causes an increase in the hepatic tryptophan pyrrolase in both the intact and the adrenalectomized rat points to the differences in the inducibility of this enzyme and tyrosine transaminase.

### Sensitive Location Reagent for the Simultaneous Detection of Sugars, Amino Sugars and Sialic Acids

Most methods for the detection of sugars on paper and thin-layer chromatograms are tedious and frequently involve the use of toxic reagents. No single location reagent so far described is capable of detecting reducing sugars, non-reducing sugars, amino sugars, and sialic acids simultaneously. In the case of thin-layer chromatography there is an additional disadvantage in that, unless a cellulose layer is used, the sensitivity of many of the reagents is reduced, probably because of the nature of the adsorbants used. Schwartz has described a very sensitive method for the detection of serine on paper chromatograms<sup>1</sup>. The chemical basis for the method is the liberation of formaldehyde from serine after periodate oxidation. The liberated formaldehyde, after condensation with acetylacetone in the presence of ammonium salt yields 3,5-diacetyl-1,4-dihydrolutidine, which is a yellow coloured, highly fluorescent compound. In his original paper, Schwartz pointed out that the reaction was not necessarily limited to serine or hydroxyaminoacids and suggested that a variety of compounds would be expected to give a positive reaction on chromatograms containing biological materials other than protein hydrolysates.

We have slightly modified the original method<sup>2</sup> and have now applied it to the location of sugars, sugar amines and sialic acid, obtained after mild acid hydrolysis of glycoproteins, or liberated from such materials after degradation by enzymes. The method offers, for the location of carbohydrates, a range of usefulness corresponding to that of ninhydrin as an amino-acid location reagent.

For paper chromatography, the dry chromatogram is dipped through a reagent containing 2 ml. 40 per cent periodic acid, 2 ml. pyridine and 100 ml. acetone. When the paper is seen to be dry, it is further dipped through a solution containing 15 g ammonium acetate, 0.3 ml. glacial acetic acid and 1 ml. acetylacetone in 100 ml. methanol. A visible yellow colour appears in 30–60 min, but yellowish green fluorescent spots can be detected within 10–15 min. For thin-layer chromatography, the method is essentially the same as that described for paper, but the reagents are used as spray rather than dip. The plates are left, after application of the first reagent, until no smell of acetone can be detected.

Hexoses and pentoses are detectable in ultra-violet light at concentrations of less than 1  $\mu\text{g}/\text{cm}^2$  and in daylight at concentrations of between 1 and 2  $\mu\text{g}/\text{cm}^2$ . Glucosamine, *n*-acetyl glucosamine, galactosamine, *n*-acetyl galactosamine and *n*-acetyl neuraminic acid are all detectable at the same level of sensitivity as the monosaccharides. When phenol was used as a solvent for chromatographic separation, the sensitivity was, in all cases, very much reduced. All other commonly used solvent systems gave perfectly satisfactory results.

Any substance capable of yielding formaldehyde after periodate oxidation will give a positive result and it is therefore obvious that the method is not completely specific for sugars and hydroxyamino acids. Indeed, the reagent might possess advantages over the other currently used reagents for the detection of formaldehydogenic ketosteroids and for some of the organic acids which are presently detectable in minimum quantities of 10  $\mu\text{g}/\text{cm}^2$ . The preliminary extraction procedures used for steroids and the ion exchange techniques for organic acids would ensure a prior knowledge of the type of compound being examined chromatographically.

### Teratogenic Response by Hamsters, Rats and Mice to Aflatoxin B<sub>1</sub>

PEANUTS and cereals may become contaminated with *Aspergillus flavus*, a mould of which the metabolites (aflatoxins) are potent carcinogens for rat liver<sup>1,2</sup>. One of these metabolites, aflatoxin B<sub>1</sub>, is a strong teratogen for the hamster<sup>3</sup>, but its effect in rats is equivocal<sup>4,5</sup>. It has been demonstrated that it binds to DNA *in vitro* and alters RNA metabolism *in vivo*<sup>6</sup>.

Although comparative teratogenesis has not been extensively investigated, results of various investigations suggest that the teratogenic behaviour of a drug in one species cannot be predicted on the basis of its effect on another. The results of the investigations reported here show that the teratogenic activity of aflatoxin B<sub>1</sub> may vary according to the species, dose and the developmental stage at which it is applied.

Virgin 8–10 week old female golden hamsters, *Cricetus auratus*, and virgin 3.5 month old C3H/He mice were used. Hamsters were mated in the evening, one couple to a cage, and observed for oestrus and copulation. Those animals which were observed to copulate were separated the next morning and the time of separation was designated as day 1 of pregnancy. To mate the mice, three females were placed with two males in a cage and observed twice daily. Zero time of pregnancy was considered to be the time when a vaginal plug appeared and the pregnant females were then placed in individual cages.

Treated animals were injected with aflatoxin dissolved in purified triethyleneglycol (1 mg/ml.); control animals were injected with equal amounts of solvent. Hamsters were intraperitoneally injected once on day 8 (closed neural tube stage)—the time when the embryos were most susceptible to the drug and likely to develop abnormalities—and on day 13 of pregnancy. Mice received intraperitoneal injections for several days during the period of rapid organogenesis which started on day 6 or 7. Animals were killed and the uterus was removed and transferred to a Petri dish containing warm saline; implantations

Table 1. INFLUENCE OF DIFFERENT DOSES OF AFLATOXIN  $B_1$  ON DEVELOPMENT OF MALFORMATIONS IN HAMSTER EMBRYOS

13	4	3	15	35	0	0	3	7.8
								24.1 $\pm$ 0.72
								1,695 $\pm$ 153
								1,632 $\pm$ 205

were counted, and each sac was opened and the contents examined under a dissecting microscope for viability, state of degeneration and gross abnormalities.

Previous tests had indicated that 4 mg/kg given on day 8 produced the greatest number of externally malformed foetuses<sup>1</sup>. When hamsters were killed on day 9, 29.4 per cent were malformed and 17.6 per cent were dead or resorbed; if killed on day 12, 23.4 per cent were malformed and 30 per cent were dead or resorbed (Table 1). Malformed live foetuses were found in all litters of these mothers. If hamsters were given 2 mg/kg and killed 1 or 3 days later, or if they were given the teratogenic dose (4 mg/kg) subsequent to the time of completion of most of the organogenesis, no malformed foetuses were found. There was a very slight increase in the incidence of dead and resorbed foetuses, but there was no difference in the size or weight of the living foetuses between controls and foetuses exposed to a dose of 2 mg/kg early in gestation or of 4 mg/kg late in gestation.

The response of C3H mice was extremely limited. Preliminary experiments with a single treatment of 8 or 12 mg/kg on day 8 of gestation resulted in the death and resorption of 90 per cent of the foetuses. Fractionated (daily) doses which produced rates of re-absorptions and deaths comparable with those obtained with hamsters were therefore used in an attempt to obtain foetuses with abnormalities. No malformations and no statistically significant differences in weight (0.05 level) were found between foetuses from control and treated mothers, but varying incidences of dead or resorbed foetuses were noted (Table 2).

Histological examination of the placenta of pregnant mice and hamsters which had been treated with solvent did not reveal any obvious differences. Moreover, the placentae of treated mothers did not show any macroscopic or histological signs of abnormality. Although there were signs of toxic injury to the liver of foetal hamsters with abnormalities<sup>2</sup>, there were no histological signs of liver injury in foetal mice which had been subjected to repeated injections of aflatoxin  $B_1$ .

It is possible that between the mouse and hamster there are differences in the metabolism of aflatoxin  $B_1$  and in the rates at which it is discharged in the faeces and urine. The amount of teratogen reaching the foetus would therefore differ in the two animals. The absence of gross malformations, growth retardation and of liver damage in foetal mice subjected to aflatoxin  $B_1$  may indicate, moreover, that differentiating tissues of the mouse and hamster differ in their susceptibility to aflatoxin  $B_1$ .

Table 2. INFLUENCE OF DIFFERENT DOSES OF AFLATOXIN  $B_1$  ON DEVELOPMENT OF MALFORMATIONS IN C3H/He MICE

Day of gestation	Treatment		Normal No.	Foetuses		Living foetuses	Weight (mg)
	Dose of aflatoxin (mg/kg/day)	Pregnant animals		No.	Per cent	Size (mm)

\* One malformed foetus was also found.

Numbers in italics refer to animal killed on day 14; all others were killed on day 18.

Butler and Wigglesworth have reported that in rats a dose of less than 200  $\mu$ g of aflatoxin  $B_1$  caused retardation of growth and a dose of 300  $\mu$ g caused foetal death with haemorrhages at the uteroplacental junction<sup>3</sup>. In another study with Wistar rats aflatoxin  $B_1$  at a dose equivalent to a quarter of the  $LD_{50}$  dose for non-pregnant female rats, a slight reduction of placental weight was found at term. On that occasion the drug was given orally rather than intraperitoneally, as with the experiments with the rat, mouse and hamster reported here. Treatment on day 16 caused a retardation in the growth of the foetuses and this was considered to be a secondary effect resulting from toxicity for the mothers or because of damage to the liver of the mothers<sup>4</sup>.

These investigations demonstrate that the teratogenic response to aflatoxin  $B_1$  is species specific. There is evidence that other teratogens such as cortisone<sup>5</sup> are species specific and even that the incidence of cleft palate induced by cortisone in mice is strain specific<sup>6</sup>. The incidence of malformations produced by trypan blue in rats varies from strain to strain<sup>7</sup> and thalidomide produces malformations in A strain mice<sup>10</sup> but not in C57BL/6 mice<sup>11</sup>.

Aflatoxin  $B_1$  was kindly presented by Richard W. Jackson, Chief Fermentation Laboratory, US Department of Agriculture, Peoria, Illinois, and by Gerald N. Wogan, assistant professor of food toxicology, Department of Nutrition and Food Science, MIT.

## Removal of Macroglobulins from Serum by Ultrafiltration through Agarose Membranes

ULTRAFILTRATION as a method for separating proteins of different sizes has been used in the past<sup>1-3</sup>, particularly in the separation of viruses from other smaller proteins<sup>4</sup>, as well as in the separation of viruses from one another<sup>5-9</sup>. The scant use currently made of this method is astonishing, for it seems much more attractive to push a protein solution through a membrane-shaped gel (ultrafiltration) than to let it seep through a column filled with grains of a

Fig. 1. Cross section of ultrafilter. *a*, Serum to be ultrafiltered; *b*, upper agarose layer, the top surface of which is provided with a skin; *c*, agarose slice, lying on the fritted glass filter *d*; *e*, adhesive tape attaching plastic collector tube *f* to stem of filter and cork; *g*, ultrafiltrate; *V*, vacuum connexion.

gel and to depend on pure diffusion for the separation of proteins of different sizes (gel filtration chromatography). These considerations induced us to attempt the separation of 19S macroglobulins (molecular weight of about 1,000,000) from the other serum proteins (molecular weight of about 160,000 and 70,000) by ultrafiltration. Such a separation, when successful, is very useful in immunohaematology, immunochemistry and immunology in general, especially where the differentiation between primary and secondary antibody forming responses is of interest.

Analytical ultracentrifugation was used to monitor the molecular weight distribution of all the serum ultrafiltrates obtained in various conditions. The membranes were made of agarose<sup>10</sup> (Seakem), a neutral derivative of agar-agar which is often used in gel filtration chromatography. Preliminary experiments had shown that the retention of macroglobulin is better the drier the atmospheric conditions during the setting of the gel. A certain degree of drying evidently conditioned the outer layer of the gel by forming a skin which determined the semi-permeability of the membrane. The exact conditions of "skinning" were determined for the purpose of preparing membranes which consistently retain all 19S macroglobulins, while allowing maximum amounts of 7S globulins, as well as albumin, to pass through them.

The best method of forming these membranes is to lay a disk of solid agarose in a Buchner funnel, and seal it with hot agarose solution, thus forming a cup-shaped membrane, in the following way. Agarose (5 per cent) (w/v) is dissolved in physiological saline by heating and stirring in a 100° C water bath. A vacuum is applied two or three times while the solution is still hot in order to remove dissolved air which might give rise to bubbles causing leaks in the membrane. To make the disk, part of the hot solution is poured into a glass tube (inside diameter of approximately 27 mm), in the bottom of which a small hole is bored after the gel has set. By blowing through the hole the sausage-shaped gel can be removed from the tube and 0.5–1 mm thick slices are easily cut off it with a wood planer. A slice is laid on the fritted glass of a Buchner funnel (inside diameter 30 mm, grade "fine" and fitted with a long stem,

which facilitates attaching the collecting tube), to prevent the pores in the fritted glass from becoming clogged up by molten agarose. (The sausage shaped gel can be used again, for cutting slices, and is best stored refrigerated.) Hot agarose solution (15 ml.) is then pipetted onto and around the slice with the aid of a Pasteur pipette with a tip which has an opening of 3 mm diameter. When the slice on the bottom of the funnel is completely covered with hot agarose solution the rest is deposited along the sides of the funnel, while it is being constantly turned around its axis, mouth downward at an angle of about 30°. When all the necessary agarose has been deposited rotation of the funnel is continued at an angle of 60°, and just before the gel sets a vacuum is applied at the stem of the funnel to draw the membrane tightly to the walls of the funnel.

When the gel has completely set, any portion protruding more than a few millimetres above the expected level of the liquid is trimmed away, to avoid undue osmotic attraction for the smaller proteins by the unwetted part of the gel. Immediately after trimming the surface skin is formed by directing the hot air stream of a hair drier for 10 sec from a distance of 25 mm, warming the rim of the filter to approximately 62° C and the inside of the funnel to 58° C. As soon as possible the serum is deposited on the membrane. The liquid should touch nothing but the membrane surface to avoid leakage (Fig. 1). A collecting tube is attached to the stem of the funnel with adhesive tape and the whole arrangement is attached to a vacuum flask and vacuum is applied (see Fig. 1).

With a vacuum of approximately 36–45 cm of mercury, 2 ml. of serum filters completely in about 4 h. When 2 ml. of serum is applied, approximately 2.2 ml. of a  $2.0 \pm 0.2$  per cent protein solution is collected as ultrafiltrate, containing the normal proportion of albumin and 7S globulin and no trace of 19S macroglobulin, as shown by analytical ultracentrifugation (Fig. 2) within the limits of resolution of this method, which can show up the presence of less than 0.01 per cent of a given protein. The absence of IgM in the ultrafiltrate was further demonstrated by immunodiffusion tests. Immuno-electrophoresis has confirmed that the principal medium molecular weight immune globulins have ultrafiltered and zone electrophoresis has shown a decrease in the  $\beta_2$  and  $\alpha_2$  bands, corresponding to the absence of  $\beta_2$ M (IgM) and  $\alpha_2$ M macroglobulins.

With anti-D (albumin-agglutinating antibody) all the activity (+ + + at 1/16) was found in the ultrafiltrate, whereas with anti-D (saline-agglutinating antibody) none of the activity (+ at 1/64) was found in the ultrafiltrate, and with anti-A<sub>1</sub> (saline-agglutinating antibody) none of the activity (+ at 1/8) was found in the ultrafiltrate. These

Fig. 2. Ultracentrifuge schlieren (60° phase plate angle) patterns of serum (below) and its ultrafiltrate (above) taken at 20 min (left) and 52 min (right) after attaining the speed of 59,780 r.p.m. The concentration of protein was 1.0 per cent in each case. The absence of 19S macroglobulin in the upper left curve is quite evident.

results were as expected; only the first mentioned antibody, a 7S immune globulin (IgG), passed the membrane while the other two, being 19S macroglobulins (IgM), were retained on the membrane. With anti-*Lub* (indirect Coombs antibody) all the activity (+ + at 1/2) was found in the ultrafiltrate. This indicates that this antibody must be a 7S immune globulin; further tests showed it to be of the IgA type<sup>11</sup>.

Preliminary tests indicate that a 10 per cent agarose membrane can be used for ultrafiltering albumin (molecular weight about 70,000), while retaining 7S globulins (molecular weight about 160,000). This result is sufficiently encouraging to attempt the separation of the *L* and *H* chains of immune globulins with agarose of an even greater concentration, a possibility which is now being investigated.

Because of the thickness of these hand made membranes, some of the serum proteins remain in the filter. They can be washed out of it at the cost of further dilution. The thickness of the agarose membrane is also the principal reason for its very slow flux. When much thinner synthetic membranes of the same pore size are made it will be reasonable to expect an increase in flux of up to two orders of magnitude, as well as a very noticeable decrease in loss of protein caused by retention inside the membrane. All known viruses are larger than 19S macroglobulins, and so the manufacture of such membranes may well be most useful for making virus free solutions in general, and in particular for the purpose of obtaining hepatitis free plasma.

This work was supported in part by a Public Health Service grant.

### Increased Permeability to Albumin induced with Protamine in Modified Gelatine Membranes

THE passage of macromolecules through living membranes is facilitated by cationic forms of proteins<sup>1</sup> and by histones, protamine and alkaline polyaminoacids as demonstrated by Ryser and Hancock<sup>2</sup>. Generally, the cell membrane surface is considered to carry a net negative charge, a property which should be especially pronounced in the case of many tumour cell surfaces<sup>3</sup>. Alterations reported in the permeability of cell membranes may be dependent on changes in membrane surface charges, caused by the adsorption of large cations. I have demonstrated that similar effects are produced by polycations on negatively charged artificial protein membranes.

Membranes were prepared from thiolated gelatine—gelatine reacted with a thiolactone according to Benesch and Benesch<sup>4</sup>. Peptide bonds are formed through the free amino groups of the protein chain and the thiolactone, resulting in addition of free reactive sulphhydryl groups to

the protein. The thiolated gelatine used ('Thiogel B' from Schwarz Bio Research, Inc.) has a molecular weight of about 100,000 and has attached twelve equivalents of sulphhydryl/100,000 g. On oxidation intermolecular cross-linking is established through disulphide bridges. The resultant increase in molecular weight gives a gel which is insoluble in water.

An 8 per cent solution of thiolated gelatine in hot M/20 triethanolamine buffer, pH 7.4, was prepared and poured into a Petri dish. The solution was ready for use after 5–10 min, and glass tubes, of inside diameter 11 mm with stoppers in one end, were dipped into the gelatinous solution. In this way a diaphragm was formed over the open end of the tubes, which were placed in a moist chamber at room temperature for 15–20 h. Melted paraffin was painted on the outer side of the tubes up to the cross-linked thiolated gelatine membranes, and they were submerged into the triethanolamine buffer. Into the tubes was poured 1 ml. of 1 per cent 'Blue Dextran' in buffer, which should not pass through the membranes.

Iodinated human serum albumin, labelled with iodine-131, was added to human serum albumin purified from commercial albumin ('Kabi') by a precipitation procedure<sup>5</sup> with 1 per cent trichloroacetic acid in 96 per cent ethanol and freed from label low molecular weight material by shaking with 'Sephadex G-25'. Protamine sulphate prepared from salmon sperm with a molecular weight of about 5,000 and 60 per cent arginine was supplied by the late Dr Paul Stroier Rasmussen. Polyornithine-HBr was purchased from Yeda Research and Development Co., Ltd., The Weissman Institute, Israel.

Continuous recording of diffusion rate was accomplished by pumping the outer solution through a coil inserted into the well-type scintillation crystal of a one channel analyser connected with a ratemeter and a d.c. recorder. The outer solution, 14 ml. of triethanolamine buffer and 5 mmolar calcium chloride, was placed in a plastic vial which was covered on the inside with thiolated gelatine in order to avoid adsorption onto the plastic. The membrane mounted on the glass tube was submerged 3–5 mm below the surface of the outer solution.

Human serum albumin labelled with iodine-131 (1 ml. of 0.2 per cent or 1.0 per cent) in the triethanolamine buffer was used as the inner solution, and when the rate of diffusion was constant, polyornithine-HBr or protamine sulphate was added to the outer solution.

The membranes probably carry a negative surface charge. This may explain the results of dialysis obtained with such membranes by Johnson<sup>6</sup>, who finds decreased diffusion of nicotinic acid and increased diffusion of an alkaloid. In order to exaggerate the negative charge, the membranes were allowed to adsorb the negatively charged azo-dye Congo red by exposing the membranes to  $2 \times 10^{-4}$  molar Congo red in buffer.

Fig. 1 shows the rate of diffusion of albumin through two comparable membranes, one of which has been submerged into Congo red. To both membranes 100  $\mu$ g of protamine sulphate was added and there was a considerable rise in the rate of dialysis through the membrane treated with Congo red. The untreated membrane was unaltered after addition of protamine sulphate. Fig. 1 also shows that treatment with Congo red decreases the diffusion rate for albumin. Table 1 shows the rates of diffusion through different sets of membranes.

The results indicate that the diffusion of human serum albumin labelled with iodine-131 is accelerated when protamine sulphate and polyornithine-HBr are added to the outer solution in experiments with membranes loaded with Congo red. This effect of polycations is not observed on untreated membranes with a relatively fast rate of diffusion for albumin. As indicated in the last line of Table 1, membranes which exhibit a slow rate of diffusion will respond in the same way as membranes loaded with Congo red, which suggests that they have a smaller negative surface charge.

Fig. 1. Continuous recordings of albumin labelled with iodine-131 in the outer solution after addition of 1 ml. of 1 per cent albumin labelled with iodine-131, total c.p.m.,  $2.55 \times 10^5$ , to tubes with cross-linked thiolated gelatine membranes submerged in 14 ml. of the outer solution at pH 7.4 at room temperature. —, Permeability of an untreated membrane; ---, permeability of a membrane treated with Congo red. The arrows indicate addition of 100  $\mu$ g of protamine (1 mg/ml.) to the outer solution.

Addition of surface active polycations like protamine sulphate to such membranes is commonly assumed to result in the adsorption of monomolecular layers of polycations to the surfaces. Thus more cationic groups are bound to the membranes and any functional behaviour caused by surface charge may be altered.

Table 1. PERMEABILITY OF THIOLATED GELATINE MEMBRANES TO LABELLED HUMAN SERUM ALBUMIN BEFORE AND AFTER ADDITION OF PROTAMINE SULPHATE OR POLYORNITHINE-HBr

Pre-treatment of membrane	Rate of diffusion of albumin before addition of polycation (mg/h/membrane)	$\mu$ g of polycation added (1 mg/ml.)	Rate of diffusion of albumin after addition of polycation (mg/h/membrane)

\* Congo red in triethanolamine buffer M/20 pH 7.4.

Finally, my data provide good evidence for the supposition that surface charge of membranes plays a part in the permeability of charged macromolecules. The present observation may prove to be of biological importance in an understanding of the process of pinocytosis in cells.

## Electron Tunnelling in Cytochromes

OXIDATION of a c-type cytochrome by light absorbed by the photosynthetic system of the purple sulphur bacterium, *Chromatium*, at the temperature of liquid nitrogen was discovered by Chance and Nishimura<sup>1</sup>. Vredenberg and Duysens<sup>2</sup> made further measurements confirming that quantum efficiencies did not change by more than a factor of two, if that much, at the lowest temperatures. The light and instrument limitations on these measurements make any further conclusions about rates difficult.

Rates not limited by light intensity have been measured with a fast spectrophotometer using a pulsed ruby laser for excitation<sup>3,4</sup>. The chief advantage of the laser compared with a flash lamp is the absence in the former of after-glow which, in the latter, interferes with spectrophotometric measurements on turbid samples for milliseconds after the flash. Our previous results, which went down to 32° K, have now been extended to 4.4° K, using a recently acquired liquid helium cryostat. Fig. 1 shows oscilloscope traces obtained at 4.4°, 4.5°, 15° and 88° K, respectively, on (separate) samples from the same batch of *Chromatium* (strain D).

The techniques used were essentially the same as those described before<sup>4</sup>, with some modifications as follows. A concentrated suspension of *Chromatium* in fresh growth medium was kept at least 5 min in the dark at room temperature in order to establish anaerobiosis and then frozen in the dark in liquid nitrogen and inserted into the measuring chamber. The cytochrome oxidation is irreversible below about 200° K. Each measurement involved the freezing of a separate sample. The measuring chamber was surrounded by helium (gas and sometimes liquid) at 1 atm., issuing through a throttle and diffusing ring from a liquid helium storage tank. The temperature of a copper block above the sample was measured with a carbon resistance thermometer whose calibration depends on the measurement at the boiling point of helium. Uncertainties in the interpolation formula used for higher temperatures set limits of about -3° to +5° K for the 15° K measurement and -0.2° to +0.5° K for the 4.4° and 4.5° K measurements. Measurement at 88° K ( $\pm 0.5^\circ$  K) was made with a calibrated platinum resistance thermometer in the copper block. In all cases the difference between the sample temperature and that of the copper block was measured with a gold-cobalt to copper thermocouple<sup>5</sup> provided by Dr Cesare Bucci.

The suspension used assayed 162  $\mu$ molar in bacteriochlorophyll. The light path through the sample was 1.6 mm. The laser was used in "normal" mode (0.5 msec burst) giving a total pulse of about 0.6 mJoules  $\text{cm}^{-2}$  at the sample at wavelength 6943 Å.

Fig. 1. Oscilloscope traces of optical density changes occurring at 422.5  $\text{m}\mu$  as a result of a pulse of laser light at 694.3  $\text{m}\mu$  in *Chromatium*. Ordinates vary from curve to curve as shown. Optical path length, 1.6 mm; bacterial chlorophyll, 162  $\mu$ molar. Upward deflexions represent decreasing optical density.

Fig. 2. Determination of half-time from the two measurements at  $4.4^\circ\text{K}$  and  $4.5^\circ\text{K}$ .

Fig. 3. Arrhenius plot of rate of laser-induced cytochrome oxidation in *Chromatium*. Numbers beside some points indicate the number of observations averaged to the single point.

The measurements of the two responses at  $4.4^\circ$  and  $4.5^\circ\text{K}$  subtracted from the asymptotes reached by them at long times are averaged and plotted in Fig. 2 on a logarithmic scale against the time after the laser flash. From it the half-time was estimated to be  $2.5 \pm 0.5$  msec.

The new data, together with those obtained before, are presented in an Arrhenius plot in Fig. 3. From this plot it is evident that there is a temperature dependent region above  $120^\circ\text{K}$  and a temperature independent region below  $100^\circ\text{K}$ . This may be interpreted as either two different cytochromes or two cytochrome pools which are oxidized in parallel or as two parallel mechanisms oxidizing the same cytochrome. The temperature dependent part falls off from a half-time of  $2\ \mu\text{sec}$  at room temperature to about  $2\ \text{msec}$  at  $130^\circ\text{K}$ , corresponding to an activation energy of  $3.3\ \text{kcal/mole}$  (ref. 4). The reaction at temperatures less than  $100^\circ\text{K}$  is almost constant at a half-time of  $2.3\ \text{msec}$  for a twenty-fold range of absolute temperature. The data would not allow an activation energy larger than  $4\ \text{cal/mole}$ .

We have interpreted the constancy of the rate of the low temperature reaction, together with its slowness, as evidence of a quantum-mechanical tunnelling of the

electron from cytochrome, presumably to bacteriochlorophyll<sup>6</sup>. We consider that the slowness indicates a barrier to electron transfer and the lack of activation energy indicates penetration through the barrier. There seems to be no alternative explanation in terms of semiconductor mechanisms the temperature coefficients of which fortuitously cancel<sup>7</sup> because of the wide range of constancy now established. It also seems unlikely that any movement of atoms is a necessary concomitant of a cytochrome oxidation which can occur at  $4.5^\circ\text{K}$ . Even in the case of proton transfers activation energies of  $2\text{--}4\ \text{kcal}$  are reported<sup>8</sup>.

The whole curve of Fig. 3 can be analysed as a single process involving tunnelling from several levels which are in thermal equilibrium. The method would be similar to that used by Fowler and Nordheim in explaining thermionic emission of electron from metals<sup>9</sup> or could be much simplified by assuming only one excited tunnelling level,  $3.3\ \text{kcal}$  above the ground state. The time course of the reaction recorded for the point at  $141^\circ\text{K}$  in Fig. 3 looks, however, bi-phasic, for the half-time plotted in Fig. 3 is an average value. If this is confirmed by further observation it will argue for separate pools not in rapid equilibrium with each other.

On purely quantum-mechanical grounds we would expect tunnelling to be important in chemical and biological transfer of electrons. The mechanism is well established in physical processes<sup>10,11</sup> and was proposed by Libby<sup>12</sup> and elaborated by others<sup>13-15</sup> for chemical electron transfers. Bell<sup>16</sup> had concluded that tunnelling should be important in hydrogen atom transfers. The penetrability decreases exponentially with the square root of the mass of the particle, and so similar barriers will be enormously more transparent to electrons. The requirements for electron transfer by tunnelling are (a) sufficiently close approach for there to be a measurable overlap of the wave function of the electron in the donor with that of the prospective wave function in the acceptor; (b) orientation suitable for overlap, if the wave-functions are not isotropic; and (c) suitably matched energy levels in donor and acceptor, considering the requirements of the Franck-Condon principle<sup>12</sup>, and phonon emission which may stabilize the process<sup>17</sup>.

The dependence on distance follows an exponential law in which the exponent to the base  $e$  is nearly equal to  $1\ \text{\AA}^{-1}$  for a barrier height of  $1\ \text{electron volt}$  (excess over the energy of the electron) and which is proportional to the square-root of the excess barrier height. (Compare Bohm's derivation of the formulae for rectangular and other barrier shapes<sup>18</sup>, and Eckart's exact solution for a special class of curved barriers<sup>19</sup>.) Thus if we assume an electron frequency (of approach to the barrier) of  $10^{15}\ \text{sec}^{-1}$  and a barrier height of  $1\ \text{eV}$ , we obtain half-times for penetration of about  $10^{-3}\ \text{sec}$  for a width of  $28\ \text{\AA}$  and  $10^{-6}\ \text{sec}$  for a width of  $21\ \text{\AA}$ . A barrier height of  $0.14\ \text{eV}$ , equal to  $3.3\ \text{kcal/mole}$ , would give a half-time of  $10^{-3}\ \text{sec}$  for a width of  $74\ \text{\AA}$ . These figures show the possibility of tunnelling over distances as large as the diameter of cytochrome  $c$ , now known to be  $36\ \text{\AA} \times 25\ \text{\AA}$  (ref. 20) but, of course, do not predict rates in specific cases where steric requirements, mismatching of energy levels, Franck-Condon limitations, or a smaller frequency of approach could act either to reduce the transmission rates or to give the same rates at smaller distances. Satisfying these requirements usually necessitates some activation energy before tunnelling can occur<sup>13-14</sup>, and this has tended to obscure the fact that a barrier is being penetrated. The occurrence of a clear cut case with zero activation energy is, perhaps, remarkable.

We propose that in general it is unnecessary to postulate any more complicated mechanism than tunnelling for moving electrons over distances of a few tens of Ångströms at the rates of biological processes. The requirement of matched energy levels may be used as a switch to forbid or allow the process and thus contribute to the specificities of donor and acceptor that are observed with cytochromes

and to the mechanisms which control electron transport for biological purposes. (The correlation of carcinogenicity of aromatic hydrocarbons with their fluorescence limits by Birks may also illustrate the necessity for matching energy levels in electron transfer<sup>21</sup>.)

### Localization of Acid Phosphatase in Oral Epithelium

THE presence of acid phosphatase in epidermis and oral epithelium has been well established by histochemical procedures such as Gomori's acid phosphatase method. Several workers<sup>1,2</sup> have interpreted the particulate distribution of the enzyme reaction as indicating the presence of lysosomes, acid phosphatase being an accepted marker for such organelles<sup>3</sup>. At an ultrastructural level, however, there have been few reports of lysosome-like bodies in these tissues. Rhodin<sup>4</sup> has illustrated lysosomes in epidermis and they have been described in epithelium in tissue culture<sup>5</sup>. Their form in oral epithelium has been discussed<sup>6</sup> but not illustrated and they are frequently seen in the dendritic Langerhans cells of this tissue<sup>7</sup>, and of epidermis<sup>8</sup>. Cytochemical studies of normal skin have shown conflicting results. Eisen, Arndt and Clark<sup>9</sup> concluded that the acid phosphatase in epidermal cells was not contained in organelles and that lysosomes played little part in the metabolic processes of human epidermal cells. Mishima<sup>10</sup>, however, showed acid phosphatase activity in vesicles containing melanin granules in epidermal keratinocytes; he termed these bodies lysosomes. Olson and Nordquist<sup>11</sup> demonstrated acid phosphatase activity in membrane-bound vesicles in human epidermis and recently<sup>12</sup> showed the presence of this enzyme in small vesicles in human epidermal cells which had taken up injected ferritin.

The work described here was carried out on oral epithelium from albino rat cheek. Thick sections, cut on a cryostat, were lightly fixed in glutaraldehyde before rinsing and incubating in a medium for acid phosphatase modified from Gomori<sup>13</sup>. Some of the tissue was treated

with osmium tetroxide before dehydration and embedding. The results from osmicated and non-osmicated sections were similar, and staining the ultra-thin sections did not affect the localization of activity.

Deposits of lead salt were frequently visible in the basal layer and prickly cells of the epithelium as discrete parallel strands (Fig. 1), sometimes with small adjacent vesicles. A few larger vesicles were seen, often close to mitochondria; in Fig. 1 the mitochondrion appears to be contained within a membrane. In the superficial prickly cells and the granular layer small deposits of lead were abundant, invariably associated with mitochondria (Fig. 2), but no activity was associated with keratohyalin granules. Some deposits appeared adjacent to the plasma membrane of cells in the granular layer. The keratinized layer contained very little intracellular activity, but a dense precipitate of lead was seen between most of the cells. Occasional cells (Fig. 3) showed a fine uniform intracellular deposit. Control sections incubated without substrate were free from lead precipitate.

The arrangement of discrete elongate deposits in the basal cells strongly resembles a Golgi system. Acid phosphatase has frequently been reported in this organelle in other tissues<sup>14-17</sup>. Larger deposits may represent pure lysosomes, and the structure in Fig. 1 may be considered a cytolysosome. The frequent association of mitochondria and enzyme deposits in the granular layer suggests that acid phosphatase plays a part in the loss of such organelles, which precedes keratinization. Activity was observed by Eisen *et al.*<sup>9</sup> at the cell boundaries of the superficial cells,

Fig. 1. Elongate lead deposits (D) in a prickly cell. A lead deposit lies next to the mitochondrion (M) enclosed in a membrane. N, Nuclei. Stained with uranyl acetate,  $\times 21,000$ .

Fig. 2. Part of a cell in the granular layer. Lead deposits are adjacent to a number of mitochondria. One deposit virtually encloses a mitochondrion (M). Unstained,  $\times 30,000$ .

Fig. 3. Section through the stratum corneum. There are intercellular deposits and one cell (C) shows a fine uniform deposit of lead. Unstained,  $\times 7,500$ .

where it may be associated with the loss of desmosome attachments and the formation of a thickened plasma membrane. Such deposits possibly originate from the vesicles observed near cell membranes in the granular layer. Striated bodies have been described in this position by Frithiof and Wersäll<sup>18</sup>. An occasional uniform deposit in a deep cell of the stratum corneum could well be a physiological expression of Brody's transition (T) cell<sup>19</sup>, in which metabolic activity is thought to occur.

The presence of acid phosphatase, presumably aggregated in Golgi vesicles and clearly associated with other cell organelles, suggests an involvement of bodies of a lysosomal nature in the metabolic activities of oral epithelium. Preliminary cytochemical work on the localization of non-specific esterase indicates a distribution in this tissue which supports our suggestions.

### Function of Copper in the Metabolism of Iron

THE importance of copper in the metabolism of iron has been recognized since Hart *et al.*<sup>1</sup> showed that rats become anaemic when fed a diet composed solely of milk, and respond to the administration of iron only if copper is

provided in addition. The observation made by a number of workers that, following the administration of copper to rats deficient in copper, the concentration of iron in their livers is reduced and that of haemoglobin increased has led to the assumption that copper is required for the utilization of iron<sup>2</sup>. The possibility that copper may be involved specifically in the release of iron from storage sites has not been investigated.

Examination of our data, obtained from experiments in which rats were fed a milk diet deficient in both iron and copper and on which treatments of copper and/or iron were superimposed, shows that rats whose rations were deficient in iron only had less iron stored in their livers and more iron circulating as haemoglobin and in the plasma than rats whose rations were deficient in both copper and iron, and led to formulation of the hypothesis that copper is required for the release of iron from storage sites. Results of subsequent experiments, one of which is described briefly here, support the hypothesis.

Twenty-two weanling rats were fed a diet deficient in both iron and copper. After 4.5 weeks on this diet all of the animals showed obvious signs of the deficiency syndrome and two, Nos. 8 and 12, died. The remaining animals were divided, on the basis of degree of depigmentation and reduction in rate of growth, into two evenly matched groups, groups A and B. Each animal was bled from the tail. Immediately following the collection of blood each animal in group A was given 200  $\mu$ g of copper in 0.25 ml. of solution; each animal in group B was given the same volume of 0.9 per cent sodium chloride; both by intraperitoneal injection. A second sample of tail blood was collected from each surviving animal approximately 24 h later. Nos. 19 and 22 died during the 24 h subsequent to injection with saline and the plasma from No. 16 (group A) was discarded because of haemolysis—no sample in which haemolysis of the red cells (sufficient to be detected by eye) had occurred was accepted.

The concentrations of iron in the plasmas of the deficient animals were so low (about 0.1 of normal) that meticulous care was necessary to prevent contamination; it was virtually impossible to prevent a slight degree of haemolysis and the figures quoted in Table 1 have been corrected for haemoglobin iron as estimated by the benzidine reaction<sup>3</sup> (S.D. of a single observation from the duplicate analyses: 4.3). The method of Giovanniello and Peters<sup>4</sup> was used, with slight modification, to estimate the concentration of iron in plasma. In samples in which sufficient material was available for duplicate analyses the standard deviation of a single observation was 3.0.

The increase in the concentration of iron which occurs in the plasmas of rats deficient in both iron and copper 24 h after the administration of copper (Table 1) is significantly higher than that which occurs subsequent to the administration of physiological saline solution (difference of mean differences 24.9 for which  $P < 0.05$  by the *d*-test) and supports the hypothesis that copper is necessary for the release of iron from storage sites.

In other experiments the time interval between injection and collection of the second sample of blood was

† 24 h subsequent to the injection of 2.25 mg of sodium chloride.

varied. Two hours after the injection of copper into deficient animals the concentrations of iron in their plasmas were slightly but significantly higher than those to which saline had been administered (difference of mean differences 12.2 for which  $P < 0.05$  by the  $t$ -test); at 18 h the difference of mean differences was 34.9 for which  $P < 0.01$  by the  $d$ -test. Forty-eight hours after the administration of copper to deficient animals no significant increase in the concentration of iron in the plasma was noted; however, the average concentration of iron in the livers of these animals was 94  $\mu\text{g/g}$  dry wt., approximately half of that of litter mates which had received no copper by injection.

Total iron binding capacity is normal in the plasmas of copper and iron deficient rats.

Statistical analysis of the results was carried out by Dr E. A. Cornish.

## Synthesis of Proteins by Alveolar Cells

ALVEOLAR cells are important because they are thought to produce surfactant<sup>1-3</sup>, a lipoprotein<sup>4-6</sup> which lines the alveoli and is responsible for much of the stability of the pulmonary airspaces<sup>7</sup>. Previous work has shown that alveolar cells induced with *M. bovis* (B.C.G.) suspended in Hanks medium can incorporate leucine into protein and that such incorporation is inhibited ( $\geq 99$  per cent) by puromycin. Extracellular radioactive protein appears during the incubations, which suggests either a non-specific release due to cell disruption, a more specific release dependent on energy or a combination of both factors<sup>8</sup>. This communication describes the release of radioactive protein into the suspending media by alveolar cells labelled with DL-leucine-1-<sup>14</sup>C and illustrates the depressive effect on this release of metabolic inhibitors.

Alveolar cells induced by B.C.G. were collected from rabbit lungs<sup>9,10</sup> and suspended in 5 volumes (v/wet weight) of Hanks solution. Fifty ml. of cells was incubated at 37° C with 0.125 mc. of DL-leucine-1-<sup>14</sup>C, specific activity 4.77. After 30 min, puromycin dihydrochloride was added to a final concentration of  $1 \times 10^{-3}$  moles/l. and the incubation continued for 10 min. The suspension was then divided into two equal portions. 2,4-Dinitrophenol ( $5.0 \times 10^{-4}$  moles/l. final concentration) in absolute ethyl alcohol was added to one batch of cells and an equal amount of ethyl alcohol alone was added to the other. Incubation was continued at 37° C and samples of 1.5 ml. were removed from each flask at one minute intervals from zero time to 10 min and maintained on ice. The cells were collected by centrifugation, the supernatant fluid was removed and assayed for protein<sup>11</sup>, and the cells were then suspended in water, homogenized and their protein content measured.

The material, assayed for radioactivity in a scintillation counter, was insoluble in cold and hot trichloroacetic acid and in ethyl ether-acetone-chloroform (2:2:1 v/v) at 50° C, but was made soluble by heating in 0.2 molar sodium hydroxide at 80° C for 30 min. All measurements are corrected for efficiency. Sufficient counts were made to have a counting accuracy of 97 per cent.

Fig. 1. Appearance of extracellular radioactive protein in media suspending cells (without dinitrophenol ■—■; with dinitrophenol ●---●).

Fig. 1 compares the rise in the specific activity of protein with time between the media of the cells treated with dinitrophenol and those untreated. The slopes of the lines were calculated by the least squares method. The correlation coefficients are 0.72 ( $P = 0.02$ ) for the media without dinitrophenol and 0.3 ( $P = 0.09$ ) for the media with dinitrophenol<sup>12</sup>. The time course of the protein specific activity of the cells was comparable in both groups. There was no rise in specific activity of the cellular protein with time, indicating that an increase in specific activity within the cells did not account for the rise in protein specific activity in the media.

To test the effect of other metabolic inhibitors on the release of radioactive protein into the suspending medium, 0.15 mc. DL-leucine-1-<sup>14</sup>C, specific activity 5.24, was incubated at 37° C with 6 ml. of alveolar cells for 30 min. The cells were collected by centrifugation and washed three times with cold Hanks solution; the supernatant fluids were discarded. The cells were suspended in 5.0 ml. Hanks solution and divided into two groups, to each of which puromycin dihydrochloride was added to a final concentration of  $2.0 \times 10^{-3}$  moles/l. In addition, potassium cyanide, potassium fluoride and sodium arsenite to  $3.0 \times 10^{-3}$ ,  $9.0 \times 10^{-3}$ , and  $4.5 \times 10^{-3}$  moles/l. respectively were added to one group of cells to depress metabolic activity (designated "inhibited" in Table 1). These two batches of cells were again incubated at 37° C for 10 min. The reactions were stopped by chilling and the cells washed as after the first incubation. The cells were again suspended in equal volumes of Hanks solution and each group then divided into three portions for incubation for 0, 10 and 20 min at 37° C. Following this, the procedures were identical to those previously described.

In a final experiment, 6 ml. of alveolar cells was incubated at 37° for 30 min with 0.15 mc. DL-leucine-1-<sup>14</sup>C. After washings and incubation with puromycin exactly as described, the cells were resuspended in Hanks media and

\* Potassium cyanide  $3.0 \times 10^{-3}$  moles/l., potassium fluoride  $9.0 \times 10^{-3}$  moles/l. and sodium arsenite  $4.5 \times 10^{-3}$  moles/l.

divided into two groups. One group, designated "control" in Table 1, was divided into three portions and incubated at 37° C for 0, 10 and 20 min. The other batch of cells, designated "0° incubation" (Table 1), was similarly divided and maintained on ice for the indicated times. Cells and media were then handled as previously described.

The rise of protein and RNA<sup>13</sup> is not different in the media supporting cells with energy production altered from that in the cells in which no attempt was made to inhibit energy metabolism (Table 1). The similarity of the amounts of protein appearing in the media of the control group and in the inhibited or 0° incubation groups suggests that interference with energy metabolism has no effect on most of the protein appearing in the media.

The increase of specific activity of the extracellular protein was always at least twice as great for the control group of cells as for its counterpart with the energy metabolism impaired (Table 1). The fall in the specific activity of protein in the media of cells incubated at 0° represents practically complete cessation of release of the radioactive protein into the media although a two-fold rise in the protein in the unlabelled media took place. The lack of further incorporation of leucine-<sup>14</sup>C into the cells with continued incubation is shown in Table 1 and is attributed to the effect of puromycin. This indicates that the differential rise in the specific activity of protein between the control and inhibited or 0° incubation media is not accounted for by a difference in the protein specific activity of the cells.

These experiments provide evidence that alveolar cells induced with B.C.G. can release newly synthesized protein into a suspending medium. This release is depressed by the metabolic inhibitors tested, which suggests that it represents active release rather than release due to cell disruption or death.

### Reduction in the Concentration of Phosphatidyl Serine in the Plasma of Birds with Avian Erythroblastosis

PLASMA  $\alpha$ -lipoprotein, obtained from birds affected with erythroblastosis, shows a slower than normal mobility in starch gel and paper electrophoresis. The protein moiety had the same electrophoretic mobility when it was derived from lipoproteins isolated by ultracentrifugation from the plasma of either normal or erythroblastotic birds<sup>1-3</sup>. This suggests that the change is in the lipid moiety. We have now observed a difference between lipid

extracts of normal and leukaemic plasma involving a phospholipid with the same chromatographic behaviour on silica gel *H* as phosphatidyl serine.

Lipid was extracted with chloroform-methanol<sup>4</sup> from red cells washed with either plasma or saline. The extracts were applied directly to the plates (thus avoiding the necessity for evaporation and re-solution in other solvents). Samples varying from 10–50  $\mu$ l. were spotted on silica gel *H* plates and the chromatograms were developed with chloroform-methanol-acetic acid-water (50:25:7:3 v/v<sup>5</sup>). All the solvents used contained 100 mg of butylated hydroxy-toluene/l. to prevent auto-oxidation<sup>6</sup>.

Plates were sprayed either with ninhydrin<sup>7</sup> to show the phosphatidyl serine and ethanol amine or with 1 per cent iodine in chloroform<sup>8</sup> or 4 per cent in phosphomolybdic acid ethanol<sup>7</sup> in order to show the lipids. Dragendorff's reagent<sup>8</sup> was used to demonstrate phosphatidyl choline. Commercially available preparations of phosphatidyl choline, phosphatidyl ethanolamine and phosphatidyl serine were used for reference. These preparations showed multiple components, but the specific component was recognized by the appropriate reagent. In the case of commercial phosphatidyl serine the contaminants were removed by column chromatography on silica gel<sup>9</sup>.

Fig. 1 illustrates a thin-layer chromatogram in which the migration of these phosphatides is compared with the migration of lipid extracts from normal and leukaemic plasma. This chromatogram was sprayed with 4 per cent phosphomolybdic acid, heated in an oven for 10 min, and the spots which appeared were outlined with a pencil point. The "phosphatidyl serine" spot from the leukaemic sample did not appear at this time but could be recognized 2 h later when the plates were photographed.

Material responsible for the spot migrating with the same speed as phosphatidyl serine was greatly reduced in erythroblastosis. In addition there seemed to be less phosphatidyl choline and phosphatidyl ethanolamine, but the reduction was not as great as for phosphatidyl serine (Fig. 1). The spot produced by "phosphatidyl serine" was at best only faintly visible when 50  $\mu$ l. of the extract of leukaemic plasma was applied to a chromatogram, but it was very obvious with only 10  $\mu$ l. of the extract of normal

Fig. 1. Thin-layer chromatogram plate of lipid extracts of normal and leukaemic plasma. The normal plasma extract was applied in 10  $\mu$ l. (*N*<sub>1</sub>) and 50  $\mu$ l. (*N*<sub>2</sub>) quantities and compared with the results following a 50  $\mu$ l. application of the leukaemic plasma extract (*L*). The positions reached by the known phosphatides (PC, phosphatidyl choline; PE, phosphatidyl ethanolamine; PS, phosphatidyl serine) used for comparison are indicated by (>).

plasma. This indicates a more than five-fold reduction of this phosphatide in leukaemic plasma.

Lipid extracts from washed red cells showed a pattern of lipid very similar to that of normal plasma extracts, except that the amount of "phosphatidyl serine" was much larger. There was no appreciable difference in the content of "phosphatidyl serine" in extracts from washed cell suspensions from normal and leukaemic bloods.

To summarize, the level of phosphatidyl serine (or a substance closely related to it) in normal plasma is greatly reduced in erythroblastosis. Lipid extracts derived from red cells from infected birds do not show this change. No claim is made that the reduction in phosphatidyl serine is specific for erythroblastosis, because we have not been able to investigate other leukoses or other diseases of the fowl in the same way. It is not yet clear whether this alteration in the concentration of phosphatidyl serine could be involved in the electrophoretic changes in plasma  $\alpha$ -lipoprotein in erythroblastosis, but further work in this direction is being carried out.

### Immediate Action of Phytochrome in Light-stimulated Lettuce Seeds

SEEDS of *Lactuca sativa* (var. 'Grand Rapids'), which we have used in these studies, require a short exposure to red light in order to germinate at 25° C. The promotive effect of red light can be completely nullified if the latter is followed closely by an exposure to far-red light. This involves the reversion of the active form of phytochrome ( $P_{FR}$ ), produced by red light, to its inactive form ( $P_R$ ). If a dark interval of more than a certain critical duration is intercalated between the red and far-red irradiations, some action of  $P_{FR}$  is permitted which is expressed subsequently as the germination of a number of seeds. After a certain period in darkness (the escape time) after red light, short far-red fails to have any inhibitory effect<sup>1</sup> and all the seeds germinate. The escape time therefore gives a physiological measure of the course of  $P_{FR}$  action in the seed population, as shown in Fig. 1 for our sample.

Little is known of the processes in seeds set in motion by  $P_{FR}$ , but in view of the work of Köhler<sup>2</sup> it seems possible that gibberellin synthesis is initiated. Using extraction methods he found that a significant increase in gibberellin-like substances occurred after only 60 min of  $P_{FR}$  activity. Thus events apparently occur in the first part of the escape time which are not expressed as germination (compare Fig. 1). We can assume that because these events involve the formation of gibberellins the amounts of the latter substances must be suboptimal for germination. If this is the case, the supply of further but still suboptimal levels of exogenous gibberellin might magnify the germination-promoting potential of the endogenous hormone which has been produced even by a short period of  $P_{FR}$  action.

In the present experiments seeds were imbibed on filter papers moistened with water in darkness at 25° C

for 1 h. They were then exposed to red light (1,800 ergs  $\text{cm}^{-2}\text{sec}^{-1}$ ) for 2 min, after which they were returned to darkness for varying lengths of time before being irradiated with far-red (700 ergs  $\text{cm}^{-2}\text{sec}^{-1}$ ) for 5 min. After the far-red treatment the seeds were transferred to other dishes containing either gibberellic acid ( $\text{GA}_3$ ) at 5, 10 or 20  $\mu\text{g}/\text{ml}$ . or water in the controls. These manipulations were carried out under a dim green safe light.

In the first experiment  $P_{FR}$  was allowed to act for 1, 2, 3 and 4 h (Table 1) before  $\text{GA}_3$  was supplied. The results show that gibberellic acid interacts with the product of  $P_{FR}$  action over these times to cause much higher germination percentages than it can when in total darkness throughout. Further, it is clear that the combined effect of  $\text{GA}_3$  and  $P_{FR}$  activity in stimulating germination is much more than additive. Because in this experiment activity of  $P_{FR}$  for 1 h is so evident, a second experiment was performed using shorter times of  $P_{FR}$  action of up to 30 min. The synergism between  $\text{GA}_3$  and the product of phytochrome activity is again apparent (Fig. 2). Surprisingly, as short a time as 5 min of  $P_{FR}$  action can easily be detected. Saturation with added  $\text{GA}_3$  at 10 and 20  $\mu\text{g}/\text{ml}$ . is achieved after phytochrome has been allowed to act for only 10 min.

Table 1. INTERACTION BETWEEN  $P_{FR}$  AND SUB-THRESHOLD CONCENTRATION OF  $\text{GA}_3$ \*

Length of $P_{FR}$ action (h)	Germination percentage	
	Observed	Calculated †
0	14 ± 3	12
1	71 ± 1	19
2	69 ± 0	35
3	91 ± 0	61
4	91 ± 2	90

\* 5  $\mu\text{g}/\text{ml}$ .

† The calculated germination percentage is the sum of the water control (Fig. 1) and the germination in darkness on  $\text{GA}_3$  alone. From this the value for dark germination on water (2 per cent) is subtracted.

One important fact emerges from these experiments; this is that the action of  $P_{FR}$  is almost instantaneous and can be revealed by this technique of supplying sub-threshold concentrations of gibberellic acid. Determinations of the escape time (Fig. 1) would indicate that, at least as far as germination is concerned,  $P_{FR}$  activity for 2-3 h is somewhat ineffectual; in fact, it now becomes clear that the action of phytochrome for only 5 min succeeds in producing highly significant changes in seeds.

Fig. 1. Time course of escape from the inhibitory effects of far-red ( $FR$ ) irradiation. Seeds irradiated after 1 h in darkness at 25° C with 2 min red light followed by 5 min  $FR$  irradiation, either immediately or after varying intervals of darkness. Controls in darkness and in red light were 2 per cent and 98 per cent respectively. Germination counted 24 h after beginning of imbibition.

Fig. 2. Interaction between  $P_{FR}$  and sub-threshold concentrations of  $GA_3$ . ●—●, Water; ○—○, 5  $\mu g/ml.$   $GA_3$ ; ×—×, 10  $\mu g/ml.$   $GA_3$ ; ●—●, 20  $\mu g/ml.$   $GA_3$ ; ○—○, calculated curve for additive effect of  $P_{FR}$  and 5  $\mu g/ml.$   $GA_3$ .

The great rapidity of action of phytochrome must be taken into account in any hypothesis of its mechanism of operation. This is borne out by the work of Fondeville *et al.*<sup>3</sup> on the phytochrome control of pulvinar movements in *Mimosa pudica*. These workers consider that the phytochrome control of gene activation as proposed by Mohr<sup>4</sup> is unlikely; our results strengthen this conclusion. If gene activation is involved in the control of germination by phytochrome it seems certain that it is not the primary effect of the pigment.

Köhler<sup>2</sup> has suggested that gibberellin synthesis in lettuce seeds is promoted by  $P_{FR}$ . This might indeed be the case; but one must conclude from our results, which indicate synergism, that  $GA_3$  itself is not produced. It still remains possible, however, that another gibberellin is formed in the seeds immediately after exposure to red light; this gibberellin would have to act synergistically with  $GA_3$ . This hypothesis therefore attributes to phytochrome a role in controlling a metabolic pathway for gibberellin biosynthesis. On the other hand, another substance which is not a gibberellin but which can interact with  $GA_3$  might be produced by  $P_{FR}$ .

It is also possible that  $P_{FR}$  induces changes in cell permeability. This could plausibly be the cause of the effects reported here where the enhanced penetration of exogenous  $GA_3$  might account for the strongly stimulating effect of a short duration of  $P_{FR}$  activity. It is interesting in this context to recall that in a number of seeds gibberellic acid is relatively ineffective unless some exposure to red light has occurred<sup>5</sup>.

## MICROBIOLOGY

### Virus-like Particles of a Fraction of Statolon, a Mould Product

STATOLON, a fermentation product of a mould, *Penicillium stoloniferum*, is capable of stimulating the production of interferon in animals and in tissue culture<sup>1,2</sup>. It was previously reported that the activity of the partially purified statolon is associated with a sedimentable anionic polysaccharide<sup>3</sup>. Attempts to refine further the statolon preparations were hampered by its low solubility and its tendency to aggregate with itself and other materials causing inactivation. Elucidation of the physical characteristics of statolon has recently been extended by means of centrifugation on sucrose density gradients and electron microscopic studies. It was found that it was possible to avoid aggregation if sodium chloride was added to the gradients and if the pH was kept near 9.

Dried preparations of statolon, dissolved in 1 per cent sodium bicarbonate, or the filtered fermentation broths, were placed on sucrose gradients for centrifugation. Two visible bands formed after centrifugation for 16–24 h. Fractions were collected and assayed for their ability to induce interferon. The assays were conducted with the mouse L-cell-vesicular stomatitis virus (VSV) system<sup>2</sup>, either directly on the collected fractions or by injecting mice with these fractions and then determining the concentration of interferon in their sera.

Electron microscopic examination of the heavy active fraction (45 per cent sucrose) revealed numerous particles of typical viral morphology. Examination of negatively stained preparations under high magnification disclosed hexagonal particles measuring about 30 m $\mu$  across (Fig. 1).

All the evidence suggests that these virus-like particles are associated with interferon-inducing activity. The heavy band contained such particles and was capable of inducing

Fig. 1. Particles in an isopycnic band of statolon. Stained with phosphotungstic acid. Scale equals 0.1  $\mu$ .

interferon in both tissue culture and animals. Adjacent fractions contained less interferon inducing activity and correspondingly fewer particles. No particles were found in the inactive fractions. These observations have been corroborated by additional combined rate zonal and isopycnic centrifugation experiments in swinging bucket rotors and with larger volumes in the zonal centrifuge<sup>4</sup>.

It would seem that the inoculated mould, *Penicillium stoloniferum*, is the source of the particles. Uninoculated media incubated for the same period as the normal statolon fermentation (5–7 days) showed neither interferon stimulating activity nor particles when examined in an electron microscope. Both the particles and the interferon stimulating activity were detected only after incubation for 4 days. Electron microscopic examination of thin sections of mycelia of *Penicillium stoloniferum* demonstrated particles possessing the morphology of those obtained by gradient centrifugation (Fig. 2).

Although some reduction of mycelial mass occurs after 6–7 days of fermentation, no evidence of true lytic action has been observed, either in fermentation broths or on agar media (W. M. Stark, W. H. Jackson, C. E. Higgins and M. M. Hoehn, unpublished results). Dr Richard Elander of these laboratories has suggested that failure to detect viral infectivity by cellular lysis could be due to the rigid cell wall of the mycelia of the mould. On the other hand, cell destruction is not a characteristic of all viruses and replication of this particle may also occur without lysis. Particles are not detected in the other band of interferon-inducing activity (30 per cent sucrose). Characterization of this fraction must await further investigation.

To the best of our knowledge this is the first time that virus-like particles have been found in association with moulds belonging to the form class Fungi Imperfecti. It is possible that two disease abnormalities of Fungi Imperfecti are caused by viruses. Lindberg<sup>5</sup> has reported the presence of a transmissible agent in *Helminthosporium victoriae*, and Jinks<sup>6</sup> has suggested that a suppressive cytoplasmic gene, which may be a virus<sup>7</sup>, causes an infectious condition in *Aspergillus glaucus*. In neither of these instances, however, has the pathogenic agent been identified. Lindegren has reported the occurrence of a phage in yeast<sup>8,9</sup>; however, micrographs of particles identified as the phage reveal structures lacking the uniformity normally associated with viruses. Hollings *et al.*<sup>10,11</sup> have clearly identified the virus that causes die-back disease in cultivated mushrooms (*Homobasidiomycetes*).

Tsuda and Tatum observed large hexagonal intracellular inclusions of ergosterol in *Neurospora crassa*<sup>12</sup>. We detected ergosterol in our heavy fraction, but it was possible to remove it by either chloroform or ether without significant loss of activity or particles.

Fig. 2. Two particles from a thin section of *P. stoloniferum* hyphae. Fixed with glutaraldehyde and then with osmium tetroxide. Scale equals 0.1  $\mu$ .

Viruses of fungi may not be so rare as was once thought<sup>13,14</sup> and it is possible that the problem lies in distinguishing them from other cellular components. Interferon assays, in combination with centrifugation on a density gradient and electron microscopic studies, may be helpful in revealing the existence of other viruses of fungi.

We thank E. L. Hayes, M. M. Hoehn, E. B. Murphy, C. B. Reimer, R. Schlegel, V. C. Spurling, R. M. VanFrank and F. Streightoff and his group for assistance in this work.

## PHYSIOLOGY

### Need for Calcium in Isoprenaline-induced Relaxation of the Depolarized Rat Uterus

THE contraction of depolarized smooth muscle induced by acetylcholine requires calcium<sup>1-3</sup>, and it has been proposed that calcium is released from a bound site and acts as an intracellular transmitter of the acetylcholine effect<sup>4,5</sup>. More recently, evidence has been presented that calcium may also be required for the action of a relaxant drug, isoprenaline, in depolarized smooth muscle<sup>6</sup>. This

Fig. 1. Isometric tension of isolated rat uterus in potassium chloride-Ringer, 25° C. Relaxation by isoprenaline (iso) given at arrows is inhibited in the presence of EGTA ( $10^{-3}$  molar). Calcium chloride ( $2 \times 10^{-3}$  molar) causes the muscle to shorten isotonically to about half its original length and restores iso responses. Barium chloride ( $2 \times 10^{-3}$  molar) produces equal shortening but fails to restore iso responses. Panels A, C, one horn; B, D, other horn. Between panels A, B and C, D, there was an interval of 80 min during which the preparation was repolarized in Tyrode solution and then again depolarized. Percentages on the top of panels are for the length of muscle in terms of maximum length under EGTA as measured on a Vernier scale. Concentrations of iso  $5 \times 10^{-8}$  in A, B;  $2 \times 10^{-8}$  in C, D.

communication provides further evidence of the essential part played by calcium in isoprenaline-induced relaxation of the depolarized rat uterus.

When an isolated rat uterus which has been depolarized by immersion in sodium-free potassium chloride- or potassium sulphate-Ringer is treated with isoprenaline it relaxes, but if a calcium chelating agent such as EDTA (ethylenediamine tetraacetic acid) or the more specific EGTA (ethyleneglycolbis - aminoethylether - tetraacetic acid) has previously been added to the solution no relaxation occurs with isoprenaline<sup>6</sup>. Chelating agents also abolish papaverine-induced relaxation. These effects of chelation seem to suggest that the removal of calcium from a strategic site has rendered the relaxant drugs ineffective, but because chelating agents themselves relax the depolarized uterus it could be objected that the failure of isoprenaline to relax further is simply due to the contractile element being already fully extended. This objection is disproved by the following experiment (Fig. 1).

The two horns of an isolated rat uterus were suspended in calcium-free potassium chloride-Ringer (145 mmolar potassium chloride, 12 mmolar potassium bicarbonate, 6 mmolar glucose) and treated with  $10^{-3}$  molar EGTA until they ceased to respond to isoprenaline. At this point calcium was added to the bathing solution of one horn and barium to the other, whereon both horns shortened maximally. After readjustment to the original tension isoprenaline was applied which then produced a relaxation in the horn treated with calcium but none in the horn treated with barium. The experiment was then repeated in a crossover arrangement with identical results.

The finding that isoprenaline relaxes the muscle contracted by the calcium but not that contracted by the barium suggests that this relaxation involves a mechanism which is specifically adapted to calcium. (In this connexion, it is of interest that I have found barium also to be a rather inefficient substitute for calcium in supporting the contractile effect of acetylcholine in the depolarized muscle.) It is a possibility that calcium is removed from the contractile element during isoprenaline relaxation and the question arises whether it is then taken up by an intracellular storage site or extruded into the extracellular space. An intracellular process seems functionally more probable in spite of the lack of a prominent endoplasmic reticulum in smooth muscle<sup>7</sup>; thus it has been found that isoprenaline relaxes the depolarized smooth muscle irrespective of the magnitude of the external calcium concentration<sup>6</sup>. An attractive hypothesis is that regional intracellular calcium shifts of opposite sign underlie contraction by acetylcholine and relaxation by isoprenaline of the depolarized uterus.

### Ionic Requirements of Synaptic Transmitter Release

THE release of a transmitter substance by the nerve impulse depends on the presence of calcium, rather than sodium, on the outside of the axon membrane. There is increasing evidence that inward movement of calcium is one of the first steps in the "electro-secretory" process. This view has been strengthened by recent experiments with tetrodotoxin<sup>1-3</sup>, which eliminates the regenerative

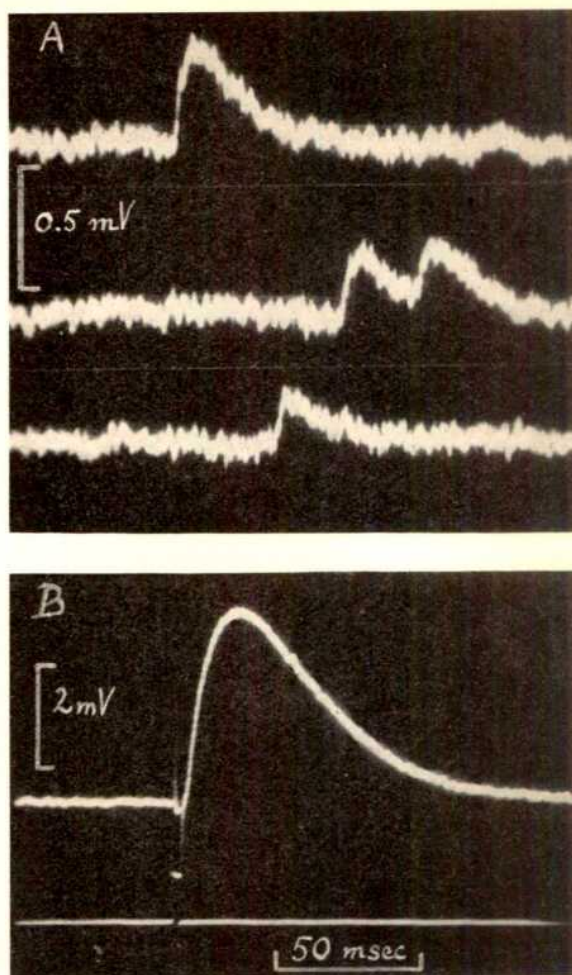

Fig. 1. Intracellular records of spontaneous miniature end-plate potentials (A), and evoked end-plate potential (B), from a frog sartorius kept in "calcium Ringer". Temperature 6.5°C. The lower trace in B shows the depolarizing current pulse (about 2 msec) applied to the nerve ending.

influx of sodium ions but does not interfere with the release of the transmitter by locally imposed depolarization provided calcium ions are present in the external solution.

Further evidence was obtained in an experiment in which a frog sartorius muscle had been equilibrated in a "sodium-free Ringer" containing 83 mmolar calcium chloride, 2 mmolar potassium chloride, and  $2 \times 10^{-6}$  g/ml. of neostigmine methylsulphate. When intracellular records were obtained from junctional regions of muscle fibres, spontaneous miniature end-plate potentials—though much reduced in size—could still be recorded (Fig. 1A). When the nerve ending was depolarized locally, by passing negative going pulses through a closely applied micro-pipette (filled with 1 molar calcium chloride), end-plate potentials were elicited similar to those previously observed in the tetrodotoxin experiments<sup>1</sup> (Fig. 1B).

Thus release of acetylcholine in response to membrane depolarization occurs in the absence of external sodium, when the sodium ions in the bath have been totally replaced by calcium.

### Induced Maturation of Gonads in *Aplysia punctata* Cuvier

STUDIES of development and reproduction in marine invertebrates are usually limited to the natural breeding seasons of the animals concerned. In order to overcome this time restriction with regard to *Aplysia punctata* (Gastropoda, Opisthobranchia), and in the hope of establishing a method which might be applicable to other animals, we tried to induce early spawning in *Aplysia* collected from a sublittoral population in Treaddur Bay, Anglesey. These collections were made in early February 1965, when the field sea temperature was  $6.7^{\circ}\text{C}$ . The natural breeding period for this species of *Aplysia* lasts from early May, when the sea temperature is about  $9^{\circ}\text{C}$ , until October, when it is about  $14^{\circ}\text{C}$  (ref. 1).

Thirty small specimens, weighing 1–8 g, representing the recruitment stock which settled in the Treaddur Bay area in early October 1964, were placed in an aquarium. The temperature of the inflowing sea water was increased during a 2 h period from the field sea temperature to an experimental temperature of  $15.0 \pm 0.5^{\circ}\text{C}$ . The animals were supplied daily with an excess of food, consisting mainly of the red alga, *Plocamium coccineum* Lamour. (which forms the bulk of their natural diet), together with smaller amounts of the red alga, *Heterosiphonia plumosa* (Ellis) Batt. Constant daytime illumination was provided.

On the first day (February 6), and at weekly intervals thereafter, two individuals were removed from the experimental group. These animals were weighed, and anaesthetized by injecting 5–10 mg of 'Nembutal' (in 1 ml. of sea water) into the regions of the cerebral ganglia and pericardium. The posterior reproductive complexes were dissected out and preserved for sectioning in either Bouin's fluid or Susa's fixative (both made up in sea water). They were then embedded in ester wax<sup>2</sup>, sectioned at  $5.0\text{--}7.5\mu$  and stained in Masson's trichrome. Control animals were collected every 2 weeks from the natural population and were treated as described for the experimental animals. Gametogenesis was then compared in the two groups.

The male and female germ cells of *Aplysia* develop side by side in the acini of the ovotestis. Spermatogenesis proceeded rapidly in the experimental animals and by the fourteenth day mature spermatozoa were present in

Fig. 1. Change in the mean diameter of oocytes in experimental (held at  $15^{\circ}\text{C}$ ) and field control (field sea temperature shown) groups of *Aplysia punctata* during the 4 weeks from February 6 to March 6, 1965. Where oocytes were asymmetrical, the maximum diameters were recorded. No copulation was seen in the field animals during this time. ●, Experimental; a, first copulation; b, single spawn ribbon; c, continuous spawning to end of experiment. ○, Field control.

Fig. 2. Size frequency distributions of oocytes in experimental (held at  $15^{\circ}\text{C}$ ) and field control (field sea temperature  $6^{\circ}\text{--}8^{\circ}\text{C}$ ) groups of *Aplysia punctata* during the 4 weeks from February 6 to March 6, 1965.

the small hermaphrodite duct which in *Aplysia* functions as a seminal vesicle. In the control animals, however, male germ cells had not developed beyond the spermatocyte stage even after 28 days. The progress of oogenesis was measured by comparing the maximum diameters of oocytes selected at random from experimental and control animals, using the presence of a germinal vesicle as the criterion for identification of the young oocytes. Fig. 1 shows the comparatively rapid increase in average diameter of the oocytes of experimental animals during 4 weeks, and the change in size distribution of oocytes in each group is illustrated in Fig. 2.

Copulation between animals held at the experimental temperature was first observed on the sixteenth day. At this time the small hermaphrodite ducts of the experimental animals were packed with mature spermatozoa, whereas the oocytes were not fully grown (Fig. 2). This type of protandry, with early copulation, has also been observed in a field population of the cephalaspid, *Retusa obtusa*<sup>3</sup>. Copulation, involving groups of two or three animals, occurred frequently from the sixteenth day until the end of the experiment. After 19 days a single spawn mass was deposited. No further spawning was observed until the twenty-third day, when oviposition occurred in several animals, and numerous spawn masses were deposited each day thereafter (Fig. 1). In comparison, field animals were first seen to copulate in mid-April and spawn was not found in the Treaddur Bay habitat until early May.

Sections of the spermatheca of an animal known to have spawned showed oocytes and spermatozoa in various stages of breakdown. This phenomenon has been described in several other species of opisthobranchiate and pulmonate gastropods<sup>4–6</sup>. All spawn deposited by the experi-

mental animals was viable, and normal veligers hatched after 11–13 days at 17°C.

The experiment was terminated after 4 weeks. During this time, certain of the experimental animals increased in weight from 8 g or less to more than 18 g, while the average weight of the field animals increased from 6 g to only 8 g (ref. 1).

## Oxygen Transport by Blood in Relation to Body Size

AN understanding of the mechanisms of oxygen transport in mammals requires a knowledge of the rate of oxygen consumption (which represents the quantity of oxygen transported), the arteriovenous oxygen concentration difference (which expresses the amount of oxygen delivered per unit of circulatory load), and the oxygen tension in mixed venous blood (which expresses the "activity" of oxygen in capillary blood). These factors have previously been compared in resting, unanaesthetized sheep and humans and a striking similarity of all three measurements was noted despite great species differences in blood haemoglobin concentration and oxygen affinity<sup>1</sup>.

A wide range of metabolic rates (expressed as oxygen consumption per kilogram body weight) is observed in different mammals and is inversely related to adult body weight. This communication compares the circulatory and haematological characteristics of oxygen supply at rest in species varying greatly in body weight, using previously published results.

In all cases the results were obtained using resting, unanaesthetized animals. Calculation of the oxygen tension in mixed venous blood requires a knowledge of the percentage saturation of mixed venous blood, and the shape of the oxyhaemoglobin dissociation curve at the appropriate body temperature and pH. Because several of the results were incomplete, it has sometimes been necessary to assume one or more of the following: (1) that the pH of mixed venous blood was 7.40 or that the carbon dioxide tension in mixed venous blood was 40 mm of mercury; (2) that the oxygen saturation of arterial blood was 97 per cent; (3) that the body temperature of the species was used by the original workers to construct the blood oxyhaemoglobin dissociation curve. The first of

these assumptions may err in a direction which leads to underestimates of mixed venous oxygen tension.

It can be seen (Table 1) that with the increase of 2,000 times in body weight from ground squirrel to cattle there is a decrease of five times in the rate of oxygen consumption per kilogram body weight. The greater tissue demand for oxygen in the smaller animals is supplied partly by increasing cardiac output per unit of body weight (as much as three times) and partly by increasing the arteriovenous oxygen difference (as much as 1.7 times). Despite the range of blood flow per unit of body weight and arteriovenous oxygen concentration difference, the oxygen tension in mixed venous blood of the seven species listed varies only from 34 to 41 mm of mercury and there is no apparent trend with body size. This relative stability of oxygen tension in mixed venous blood is indeed remarkable when the variations in the blood haemoglobin concentration and the affinity of the blood for oxygen (expressed as  $P_{50}$ , the oxygen tension necessary to half-saturate the blood with oxygen) are taken into account.

The oxygen tension of mixed venous blood reflects the oxygen tension in capillary blood, not of any particular tissue but of a hypothetical integrated mean body tissue. An assumption made in using this as an index for comparing the "mean capillary  $P_{O_2}$ " between species is that there is a relatively constant activity of homologous tissues at rest in the different species. The oxygen tension in capillary blood is directly related to the pressure head for diffusion of oxygen to the sites of its utilization within the cells. Looked at in this way, smaller animals are able to deliver more oxygen to their tissues although the pressure head for oxygen delivery from capillary blood to tissue cells is not demonstrably higher than that seen in larger animals.

On the basis of measurements on three species, Krogh<sup>11</sup> suggested that smaller animals supply the additional oxygen per unit of tissue weight by having smaller intercapillary distances than larger animals. Schmidt-Nielsen and Pennycuik<sup>12</sup>, however, were only able to show an increase in capillarity in very small mammals. Schmidt-Nielsen and Larimer<sup>9</sup> suggested that a mechanism for supplying the higher oxygen need in smaller mammals might be a higher unloading tension for oxygen, because at the same percentage saturation the oxygen tension is usually greater in the smaller animals. We believe, however, that the concept of a constant percentage oxygen saturation in mixed venous (or capillary) blood is an unrealistic criterion for comparing *in vivo* unloading tensions in species of different sizes, because the arteriovenous oxygen difference and oxygen capacity vary among species, and the latter factor is not related to body weight.

We wish to support Krogh's<sup>11</sup> original hypothesis; the relationship between oxygen consumption and body weight is usually presented on logarithmic axes, and then appears as a straight line. In Fig. 1 the relationship is presented on arithmetic axes and an interesting point emerges from the resulting hyperbola: not until body weight decreases below about 1 kg do great increases in oxygen consumption per unit of body weight occur. In this region of animal size (rat, mouse and bat), Schmidt-Nielsen and Pennycuik<sup>12</sup> demonstrated an inverse relationship between muscle capillary density and body weight. They failed to find any distinct relationship in species above this body

Table 1. OXYGEN TRANSPORT BY BLOOD IN VARIOUS MAMMALIAN SPECIES IN THE RESTING STATE

Species	Body weight (kg)	O <sub>2</sub> capacity (vol. %)	$P_{50}$ (mm Hg)	O <sub>2</sub> consumption (ml./kg./min)	Cardiac output (ml./kg./min)	CaO <sub>2</sub> -CvO <sub>2</sub> (vol. %)	$P_{vO_2}$ (mm Hg)	Assumptions*	References
Cattle	414	13.8	30.8	4.2	105	4.0	40	a, c, d	2, 3
Human	75	19.6	28.8	4.1	99	4.1	39.4		4
Sheep	62	11.4	40.6	4.4	96	4.7	40.6		1
Dog	22	19.6	29.1	9.6	154	6.3	36	a, c, d	3, 5
Rabbit	1.9	16.5	34	13.2	218	6.1	38	a, e	3, 6, 7
Rat	0.4	19.6	32	18.3	286	6.4	40	b, c, d	8, 9
Ground squirrel	0.22	19.5	26.8	20.1	313	6.6	34	a, e	10

\* Assumptions made for calculation of mixed venous blood O<sub>2</sub> tension are identified as follows: a, mixed venous blood pH = 7.40; b, mixed venous blood carbon dioxide tension = 40 mm of mercury; c, arterial blood saturation = 97 per cent; d, body temperature = 37°C; e, body temperature = 39°C.

Fig. 1. Relationship between body weight (kg) of mammals and total resting oxygen consumption (ml./kg/min), based on the equation of Kleiber<sup>12</sup>.

weight. One could postulate that only in animals below a certain size (about 1 kg) does the increased oxygen need of smaller species reach a magnitude where a detectably greater capillary density is needed. In animals above 1 kg in weight variations with size in the rate of oxygen delivery per kilogram are small, and similar magnitudes of variation in capillary density may not be detectable by the present methods.

We have made no attempt to extend the generalization of similarity of mean capillary blood oxygen tension to conditions other than those seen in the resting, unanaesthetized animal. Neither have we extended the relationships noted here to specific organs, tissues or cellular components of the body.

From a comparative standpoint, it is not surprising that mixed venous (and capillary) blood  $P_{O_2}$  is maintained at similar levels over the small range of evolution represented by these mammals. It would, rather, be surprising to find, in view of the identity of respiratory enzymes over much wider ranges of evolution, that wide variations in capillary oxygen tension did occur under resting conditions.

This work was supported in part by a training grant and two research grants from the US Public Health Service, and by the Oregon Heart Association.

### Stimulus Response Curves of Single Carotid Body Chemoreceptor Afferent Fibres

STUDIES of the characteristics of activity recorded from single carotid body chemoreceptor afferent fibres have so far been concerned with the statistics of the pattern of discharge and the effects of drugs<sup>1-3</sup>. There

has been no adequate description of the activity of single fibres in response to independent changes in blood gas tensions and pH for extended ranges, and it is unclear whether or not the multifibre response curves described by Hornbein and Roos<sup>4</sup>, for example, are composed of a spectrum of differently shaped single fibre response curves showing an array of thresholds. Accordingly, we have investigated the effects of changes in arterial  $O_2$  and  $CO_2$  tensions and pH on the rate of discharge of single chemoreceptor afferent fibres dissected from the sinus nerve of the cat. The animals were anaesthetized with 0.6 ml./kg of 'Dial-Urethane', paralysed with 5 mg/kg of gallamine triethiodide and artificially ventilated. The arterial blood pressure and oxygen tension and end-tidal carbon dioxide tension were continuously recorded on a Grass polygraph. Arterial blood samples were taken for measurement of pH and carbon dioxide tension, which were changed by intravenous administration of 1 molar sodium bicarbonate, 1 molar ammonium chloride or 0.1 normal hydrochloric acid and by appropriate changes in rate and volume of artificial ventilation. The arterial oxygen tension was altered by varying the oxygen content of the inspired gas. Single chemoreceptor afferent nerve impulses were displayed on an oscilloscope and their frequency of discharge was monitored with a ratemeter whose output was recorded on the Grass polygraph. After a change in arterial  $PO_2$ , and, in particular, after a change in either  $PCO_2$  or pH, an average 15–20 min were spent in adjusting the respiratory pump level or infusion until a new steady level of discharge, measured with the ratemeter, was obtained. After a further 5–10 min at this level, the fibre activity was photographed on moving film for 20 sec periods. The numbers of potentials in 10 sec periods were later counted from the filmed records and these counts were used to construct the graphs which show response curves.

The responses of thirteen single chemoreceptor afferent fibres (from five cats) to changes in arterial oxygen tension were recorded at constant arterial blood pH and  $PCO_2$ . Each graph of discharge rate against oxygen tension for a single fibre was similar to a rectangular hyperbola (Fig. 1). In general, the rate of change of discharge with an incremental fall in arterial oxygen tension was almost zero at high oxygen tensions (above 150–250 mm of mercury and up to 650 mm of mercury). Thus response curves of single units formed a spectrum of curves such that below a characteristic  $P_{aO_2}$  in the range 150–250 mm of mercury (mean 180 mm of mercury) the rate of discharge increased progressively from 0.5–5 impulses/sec to 20–25 impulses/sec at arterial oxygen tensions of 25–50 mm of mercury. The rate of discharge at high oxygen

Fig. 1. Graph of activity (i.p.s.) against  $P_{aO_2}$  (mm of mercury) for a single chemoreceptor afferent fibre dissected from the cat sinus nerve. The  $P_{aCO_2}$  was 37 mm of mercury throughout. The line was drawn by eye.

Fig. 2. Graph of activity (impulses/sec) plotted against alveolar carbon dioxide tension (mm of mercury) for a single chemoreceptor afferent fibre of the cat sinus nerve. The  $P_a\text{O}_2$  was 115 mm of mercury, and the arterial pH was 7.30 throughout. The line was drawn by eye.

tensions was in part dependent on the  $P_a\text{CO}_2$  but may also in part be a property of the receptor complex leading to the afferent fibre being investigated. The response curve was shifted to the left by a decrease in  $P_a\text{CO}_2$  or an increase in pH and to the right by opposite changes in these variables. In addition, the discharge persisted at a  $P_a\text{O}_2$  of 650 mm of mercury even when the pH was increased to 7.6. Thus the chemoreceptors could not be shown to have a threshold oxygen tension at which firing commences.

There is a conflict in the literature over the question of the effect of carbon dioxide on the activity of chemoreceptor afferents. Joels and Neil<sup>5</sup> reported that this gas excited these afferents, but Hornbein and Roos<sup>4</sup> did not confirm this. We have tested the effect of changes in carbon dioxide *in vivo* for the range 20–60 mm of mercury while the arterial pH and  $P_a\text{O}_2$  were kept constant. The activity of single chemoreceptor fibres increased with the  $P_a\text{CO}_2$  (Fig. 2) and the slope of this increase depended in part on the pH and was sometimes steeper at a low pH (7.0–7.1) than at a high pH (7.5–7.6). The increase in response to increased carbon dioxide was observed at oxygen tensions up to 250 mm of mercury, the highest  $P_a\text{O}_2$  studied.

The effects of changes in arterial pH on the activity recorded from single fibres at constant  $P_a\text{CO}_2$  and  $P_a\text{O}_2$  were also examined. For the range of pH 6.9–7.6 there was always an increase in the discharge as the pH was decreased. The graph relating the two parameters was usually linear, but in some cases the slope increased as the pH became less than 7.1.

In the whole animal, there are factors that can complicate the relation between rate of chemoreceptor discharge and a given stimulus. Thus at low oxygen tensions it is difficult to obtain a stable arterial blood pressure and, further, there may also be an increase in sympathetic activity, both of which can increase the activity of chemoreceptors<sup>6–8</sup>. The same may also apply to extremes of  $P_a\text{CO}_2$  and arterial pH. Thus the shapes of the response curves *in vivo* are contingent on a number of other variables and do not necessarily represent accurately the response characteristics of the receptor. What is demonstrated is the complex nature of the response of the carotid body for the normal working range of the modalities that excite its activity.

Our experiments show that the response curve relating discharges of the chemoreceptor of the carotid body to changes in oxygen tension is a continuous one. Each individual response curve has a hyperbolic form, and the hyperbola found with multifibre strands does not arise from the superposition of single unit response curves of non-hyperbolic form showing clear cut thresholds. An increase in nerve activity above basal activity com-

mences at a point which varies among fibres and could perhaps be the threshold of the carotid body for the reflexes evoked by changes in oxygen tension, a reflex threshold to be distinguished from a receptor threshold. There seems to be no chemoreceptor threshold for  $\text{PCO}_2$  and pH, for the response is approximately linear in the ranges investigated. Clearly the threshold for any reflex effects produced by excitation of these afferents is also dependent on the behaviour of neurones in the central nervous system.

## RADIOBIOLOGY

### Age Dependence of Radiation Sensitivity of Haemopoietic Cells in the Mouse

DURING a long-term study of the effect of age at exposure on the incidence of leukaemia after whole-body irradiation, the age dependence of cell killing of the haemopoietic cells of the mouse was investigated. The variation of radiosensitivity with age has been described previously<sup>1</sup>, using as an end-point the  $LD_{50/30}$  days mortality, and might reflect a variation of the radiosensitivity of haemopoietic cells, because death after midlethal doses of radiation is caused mainly by their injury. To test the radiosensitivity of these cells and its dependence on age the following investigation was carried out.

SAS/4 mice, male and female, of two age groups (6 and 30 weeks old) were used. Two methods for assaying haemopoietic stem-cell survival were employed—techniques which involve the endogenous and the exogenous (or transplantation) spleen colonies, first described by McCulloch and Till<sup>2,3</sup>. The technique involving endogenous colonies is based on the fact that mice irradiated with doses of 400–900 rads develop macroscopically visible nodules (colonies) in their spleens approximately 10 days after irradiation. In the technique involving exogenous spleen colonies recipient mice were first exposed to a whole-body dose of radiation which reduced their endogenous spleen colonies to a very small number. Between 2 and 6 h later they received by intravenous injection a known number of nucleated bone marrow cells, obtained from donor mice, which had been exposed to doses of between 0 and 500 rads. Ten days later the mice were killed and the number of colonies in their spleens were counted.

The mice were irradiated with the electron beam of the 15 MeV linear accelerator at Saint Bartholomew's Hospital, at a dose rate of approximately 400 rads/sec. Four mice were irradiated at a time, each in individual 'Perspex' tubes. The remote control mouse machine, previously described, was used for location of each box in the correct position for the irradiation<sup>4</sup>.

The number of mice surviving ten days after irradiation was as follows: 122/179 (69 per cent) for 6 week old mice and 116/171 (67 per cent) for 30 week old mice, when the exogenous technique was used; and 80/108 (74 per cent) for 6 week old mice and 133/155 (86 per cent) for 30 week old mice with the endogenous technique. These values are within the upper limits of what is described as excellent survival in the best circumstances<sup>5</sup>.

For the endogenous technique, the results were expressed as the observed number of endogenous colonies after irradiation as a function of dose. When the exogenous technique was used, the results were expressed as the fractional survival of the transplanted colony-forming cells, exposed to different doses.

The combined results for both techniques are shown in Fig. 1a and b. They have been expressed in the form of cell survival curves because each colony derives from one single cell. Cytological evidence for this is given in the literature<sup>6</sup>.

The results from both techniques were combined, because the slopes of the survival curves were found to be the same within statistical errors. Thus for the 6 week old group, the  $D_0$  values were 93 and 95 rads for the exogenous and endogenous techniques respectively. The corresponding results for the 30 week group were 122 and 129 rads. The weighted average  $D_0$  values obtained from Fig. 1a and b are  $93.9 \pm 4.6$  rads and  $126.2 \pm 6.0$  rads for the 6 week and 30 week groups respectively.

This difference between the  $D_0$  values for the two ages is statistically highly significant, and fits well with the previously reported age dependence of radiation sensitivity at these ages using the  $LD_{50/30}$  days as the end point<sup>1</sup>. The data are also in general agreement with those given in the literature for the same or similar types of cells (compare refs. 7 and 8) although no dependence on age of the radiation sensitivity of these cells has previously been reported, except for colony-forming cells deriving from foetal liver<sup>9,10</sup>. In this system, however, there are many other biological differences in addition to the age. For example, it has been shown that a large proportion (about 40 per cent) of colony-forming cells of foetal liver are in the synthetic phase of the cell cycle, whereas for normal adult bone marrow the proportion of such cells is very small<sup>11</sup>.

The data of Fig. 1a and b give extrapolation numbers of  $2.47 \pm 0.64$  and  $1.42 \pm 0.33$  for the 6 week and 30 week groups respectively. More measurements are required to determine whether this difference is significant. If it were, it might be explained as the result of the accumulation of "faults" with age, thus necessitating fewer events to inactivate the cells in older mice<sup>12</sup>.

Fig. 1. Survival curve for cells from mice exposed at the age of (a) 6 weeks, and (b) 30 weeks. ●, Exogenous technique; ○, endogenous technique.

### Prevention of Radioleukaemia by Lymph Node Shielding

IN mice subjected to a schedule of irradiation normally producing a high yield of leukaemia of the thymic lymphoma type, it has been shown that the administration of foetal haemopoietic tissue leads to the presence of dividing cells (which have the chromosome characteristics of the donor almost exclusively) in the target organs of the hosts<sup>1</sup>. A related finding is a significant drop in the mortality from leukaemia. Kaplan has attributed the phenomenon of a lowered incidence of radioleukaemia resulting from the intravenous administration of bone marrow to a bone marrow factor<sup>2</sup>. It has been thought, as a more recent alternative, that inhibition of radioleukaemia follows repopulation of haemopoietic tissues and thymus by unirradiated donor cells<sup>3</sup>. The incidence of the leukaemia induced by radiation which appears to have its origin within the thymus is paradoxically unaltered by the intravenous administration of lymph node material in dissociated form. Other cells intimately associated with the lymph node but difficult to dissociate from its structure may have been excluded in the preparation of such lymph node inocula. Because of this exclusion, and because feedback mechanisms may implicate the endothelial cells of the post-capillary vessels in lymph nodes and perhaps littoral cells<sup>4</sup>, the place of whole lymph node *in situ* in altering the pattern of leukaemia induction was tested.

Exteriorization of lymph nodes<sup>5</sup> as an open wound procedure was not suitable because, in order to induce an incidence of approximately 70 per cent of leukaemia in *C57BL* hybrids, it is necessary to give four divided fractions of 200 rads  $\gamma$ -radiation at intervals of 4 days. Under sodium amytal anaesthesia an incision was made over the lumbar spine and blunt dissection carried down in the subcutaneous tissue until the inguinal node on the right side was exposed. Under direct vision the node was incorporated, by the teeth of a 13-mm Michel clip fastened from outside, in a fold of skin. The dorsal incision was then closed with silk. Again under anaesthesia on each of four occasions, a silk thread was passed through the loop of the Michel clip and traction applied to it so that the fold of skin containing the lymph node was manoeuvred under a 5-cm thick lead block. The lead block was recessed to take the clip and fold of skin. Ties to the extremities and the tail enabled the remainder of the body of the mouse to be pulled clear of the lead shielding during exposure to gamma rays. Seven (*C57BL*  $\times$  *CBA.T6T6*)<sub>F</sub> female hybrids between 30 and 40 days

Fig. 1. The incidence of radiouleukaemia in *C57BL* hybrid mice following four fractions of 200 rads  $\gamma$  radiation in relation to time following: no further treatment (●—●); intraperitoneal lymphoid tissue (○—○); intraperitoneal haemopoietic tissue (△—△); lymph node shielding (×—×). (The mice are syngeneic, the *CBA* element having been derived from the backcrossing of *T6T6* mice to *CBA/H* by Dr Mary Lyon.)

of age were subjected to the leukaemogenic schedule of irradiation with a single lymph node excluded from the radiation field by this closed procedure. Death occurred at the following times after irradiation from the following causes: at 231 days, aplastic anaemia; at 576 days, ovarian tumour; at 670 days, reticulosarcoma; at 747 days, mammary tumour; and at 776 days, probably aplastic anaemia. Two mice were still alive at 800 days after irradiation. Approximately 70 per cent of mice given the fractionated radiation without lymph node shielding could be expected to die from thymic lymphoma within 365 days of the last irradiation (Fig. 1). Thirteen and fifteen mice so irradiated received near to  $10^7$  cells of foetal liver and lymph nodes respectively by the intraperitoneal route from (*C57BL*  $\times$  *CBA/H*) $F_1$  female hybrids. As expected, the incidence of radiouleukaemia remained high in the latter. A confirmatory experiment involving thirteen (*C57BL*  $\times$  *CBA.T6T6*) $F_1$  females between 30 and 40 days of age given the leukaemogenic schedule of irradiation and amytal anaesthesia during irradiation, and eleven so treated but with a single lymph node excluded from the irradiation field, gave the following results: 365 days after irradiation six of the former had succumbed to thymic tumours (at 141, 153, 157, 162, 171 and 230 days) and two only of the latter (at 192 and 207 days). Combining the results of the experiments, two of eighteen mice irradiated with a lymph node shielded died from thymic lymphoma (an incidence of some 11 per cent).

It is well known that lymphoid tissue is among the most sensitive to ionizing radiations and it seems clear from these experiments that maintenance of even a small amount by shielding during irradiation is a potent factor in hindering the onset of radiouleukaemia. The place of bone marrow<sup>2</sup> has dominated discussion in this field, although the efficacy of spleen shielding had been demonstrated by Lorenz, Congdon and Uphoff<sup>3</sup>, and Wallis, Davies and Koller<sup>4</sup> have recently reported the effectiveness of spleen cells administered intravenously. Bone marrow

colonization is proceeding within a week of bone marrow grafting, but it is not until three weeks later that an increased mitotic rate in the thymus enables the penetration of donor cells into this organ to be seen<sup>1</sup>. Failure of haemopoietic tissue entirely to prevent lymphoma may result from failure of the colonizing cells completely to outgrow the persisting cells of the host exposed to the leukaemogen, with or without a subcellular mechanism operating. Also during the third week after irradiation the weight of the lymph nodes approaches pre-irradiation levels and may incidentally be a pointer towards direct colonization of lymph nodes from the marrow without a thymic intermediate phase. It seems that early restoration of some immunologically competent cells following haemopoietic grafting is likely to be the important factor and may be the mechanism lowering the incidence of radiouleukaemia by contending with rogue cells or preventing activation of latent virus.

The investigation was sponsored by the New South Wales State Cancer Council.

## CYTOLOGY

### "Phagocytic" Lysosomes in Chromatolytic Neurones

SEVERAL investigators have demonstrated that cells possess a mechanism for the bulk segregation and digestion of portions of their own cytoplasm. Such a mechanism is generally known as "cellular autophagy"<sup>1</sup>, and the digestion of endogenous material is accomplished within vacuoles limited by membranes known as cytolysosomes<sup>2</sup>, cytogrosgosomes<sup>3</sup> or autophagic vacuoles<sup>4</sup>, which show a positive staining reaction for acid phosphatase.

The origin of the membrane surrounding autophagic vacuoles is a matter for speculation. The suggested sources include Golgi cisternae<sup>5</sup> and agranular endoplasmic reticulum<sup>6,7</sup>, or by *de novo* synthesis in the ground cytoplasm<sup>8,9</sup>. The manner in which acid hydrolases enter autophagic vacuoles is also speculative. According to Novikoff *et al.*<sup>6</sup> the enveloping membrane is formed by fusion of vesicles which actually contain the hydrolases although fusion with another lysosome has also been suggested<sup>5</sup>.

Considerable cellular autophagy occurs in neurones after axon section. During an investigation into the fine structural changes associated with axon section in neurones of the superior cervical ganglia in the rabbit, a new mode of formation of autophagic vacuoles was revealed and is reported here. The sectioned ganglia were fixed in acetate-veronal buffered osmium tetroxide, embedded in 'Araldite', and all thin sections were stained with lead citrate.

The neurones responded promptly to axon section by an increased production of small, dense bodies identified as primary lysosomes by the localization of acid phosphatase activity within them, using the Gomori lead phosphate technique<sup>10</sup>.

After 7 days the primary lysosomes had increased in size and were either round, ovoid or disk-shaped with

the periphery thicker than the central region (Fig. 1). Frequently the disks were curved, presenting goblet-shaped profiles (Fig. 2). In many instances a primary lysosome had completely enclosed a small region of cytoplasm and presented a ring-shaped profile the centre of which contained clearly recognizable ribosomes (Fig. 3). Primary lysosomes were also frequently observed partially surrounding mitochondria. Fourteen days after axon section the preponderant type of lysosome was the "cytosome", or irregularly shaped structure bound by a membrane and containing regions of variable electron density, dense membranes and usually a band of extremely dense material around all or part of the periphery (Fig. 4).

These observations suggest that, in chromatolytic neurones, primary lysosomes behave in a "phagocytic" manner, engulfing small regions of cytoplasm, clusters of ribosomes and possibly even mitochondria. By this mechanism structures are formed which are clearly autophagic vacuoles, for they contain recognizable cell organelles, possess acid phosphatase activity and are surrounded by a membrane. The material that is phagocytosed is contained within a vacuole the membrane of which is part of that of a primary lysosome and therefore, of necessity, impermeable to hydrolytic enzymes. This poses the question of how the acid hydrolases reach the engulfed materials in order to digest them. Some change in property of the membrane may occur, allowing diffusion of enzymes into the enclosed region, or the membrane

may dissolve. The next stage in the process of digestion is then represented by cytosomes.

### Evidence of Age Aneuploidy in the Chromosomes of the Sheep

VARIATIONS in chromosome counts associated with age were first shown in human leucocyte cultures by Jacobs *et al.*<sup>1</sup>. I have examined the chromosomes of twenty-two normal ewes and rams and six freemartin sheep in preparations made by a method similar to that of Basrur and Gilman<sup>2</sup>, and have counted chromosomes in at least fifty metaphases in each case. Several cultures were prepared from each freemartin and were then counted to see if there was a relationship between XY cells and the degree of masculinization as reported before<sup>3,4</sup>; these results are reported elsewhere<sup>5</sup>. In none of the twenty-two normal sheep was any chromosome abnormality observed; in the freemartin sheep, however, there was XX and XY white blood cell chimaerism. The chromosome counts of the six freemartin sheep are recorded in Table 1 and the percentage of hypomodal and hypermodal modal cells in each of these are given in Table 2.

Most of the normal sheep were lambs less than 1 yr old; the oldest case was a Suffolk ram aged 2 yr. Only one freemartin was younger than 2 yr old (Table 2) and the others were aged from 4 to more than 7 yr. In most countries breeding ewes are culled after three or four mating seasons, which means that the usual culling age is 6 yr. While sheep are recorded as living for up to 15 yr<sup>6</sup> it must be assumed that a culling age of 6 yr has evolved with time and that the majority of sheep age rapidly after this. This is usually shown by wear of the teeth. It is reasonable to assume, therefore, that the five freemartin sheep aged 4-7 yr were significantly older than the twenty-two normal sheep which I used.

When the chromosome counts of the five older freemartin sheep were compared with those of the normal

XX and XY chromosomes were counted on cells with 54 or 55 chromosomes and tetraploid cells only.

Table 2. CHROMOSOME COUNTS FROM SIX FREEMARTIN SHEEP SHOWING PERCENTAGE OF MODAL AND NON-MODAL CELLS

Sheep	Age	No. of cells examined	% Hypo-modal (50-53)	% Modal (54)	% Hyper-modal (55)	% Polyploid (1)
Freemartin 6	18 mths	206	9.22	90.29	0.47	0.0
Freemartin 5	4 yr	303	11.55	85.48	1.65	1.32
Freemartin 4	5 yr	160	13.12	83.13	1.88	1.88
Freemartin 1	5 yr	167	19.16	78.44	0.00	2.39
Freemartin 3	7+ yr	409	17.84	78.24	1.96	1.96
Freemartin 2	7+ yr	204	20.58	74.02	1.97	3.4

Table 3. COMPARISON OF CHROMOSOME COUNTS OF TWENTY-TWO NORMAL SHEEP WITH FIVE FREEMARTIN SHEEP

	Ages	Total cells examined	Hypomodal		Modal (54)		Hypermodal (55)		Polyploid	
			No.	%	No.	%	No.	%	No.	%
Normal sheep	2 years	1,831	198	10.81	1,602	87.49	6	0.33	25	1.37
Freemartin sheep	4-7+ years	1,243	203	16.45	994	79.86	20	1.49	26	2.20
% Difference				+5.64		-7.63		+1.16		+0.83

Comparison of normal and freemartin sheep, regarding this table as a contingency table and using a significance level of 0.05, produced significant values of  $\chi^2$  for the whole table (38.98 with a distribution frequency of 3) and for the proportions of hypomodal, modal and hypermodal cells (19.87, 31.93 and 14.51 respectively with a distribution frequency of 1). The numbers of polyploid cells did not show a significant deviation from their expected values. ( $\chi^2 = 2.40$ , and distribution frequency was 1.)

sheep, a very significant increase in both hypomodal and hypermodal cells was recorded (Table 3). Although small groups of animals are considered it is pertinent that the sixth freemartin sheep, aged 18 months, showed a modal chromosome count which was near to that of the normal younger sheep. In this case only one genuine hypermodal cell was recorded. Furthermore, the two oldest sheep were between 7 and 8 yr old and the number of hypermodal cells (fifty-five chromosomes) was eight and five respectively, which is more than double that recorded from all the normal sheep together. Photographic karyotypes of all the hypermodal cells showed that the extra chromosome was always a member of the acrocentric group (Fig. 1) and both male and female cells were seen.

The biological mechanisms contributing to age aneuploidy have been discussed by Jacobs *et al.*<sup>1</sup> and the same factors could have applied to the sheep. Possibly the increase in aneuploidy was the result of "adaptation" between chimaeric blood cells as considered by Basrur and Stoltz<sup>2</sup> in the bovine freemartin. In the latter case, however, a high percentage of abnormal metacentric cells was seen in all preparations, together with a large number of defective cells showing chromatid breaks, particularly in donor cells. In the freemartin sheep, no observable increase in chromatid breaks was seen in any of the preparations and, out of 1,449 metaphases counted, on only three occasions were abnormal chromosome patterns recorded (Fig. 2). These are apparently seen in human mitotic preparations (personal communication from Ferguson-Smith) and could have arisen in culture in the same way as the translocation reported by Trujillo *et al.*<sup>3</sup>.

It would seem, therefore, that these observations are the same as age aneuploidy reported in man, but they can be

Fig. 2. Triad fusion of three acrocentric chromosomes, presumably caused by breakage and reconstitution of fragments.

confirmed only when larger numbers of normal sheep of differing ages are compared as well. An apparent and interesting difference that has not previously been reported in the sheep or any of the higher domestic animals is, however, suggested.

### Mitogenic Property of *Wistaria floribunda* Seeds

Two phytomitogens have been described which stimulate blastogenesis and mitosis of human peripheral blood lymphocytes: phytohaemagglutinin (PHA) from *Phaseolus vulgaris*<sup>1</sup> and pokeweed mitogen (PWM) of *Phytolacca americana*<sup>2</sup>. Recently we have discovered mitogenic properties in seed extracts of *Wistaria floribunda* (syn.: *Wisteria floribunda*, Japanese wisteria).

Peripheral blood buffy coat cells of ten normal volunteers were cultured by the method previously described<sup>2</sup> in the presence of saline extracts of *Wistaria floribunda* seeds (final dilution of extract 1:1,500), pokeweed mitogen (Grand Island Biological Company, final dilution 1:1,500), and in the absence of a phyto-mitogen. Cultures were sacrificed at 48 and 72 h and studied for morphology with the Wright-Giemsa stain and for histochemical characteristics.

Haemagglutination was not discernible in cultures prepared with extracts from the seeds of *Wistaria floribunda*, but leukagglutination was apparent. Morphologically and chronologically the blastogenesis occurring in these cultures appeared identical to that induced by pokeweed mitogen. By the time the cells had been cultured for 72 h, mitotic cells were abundant. No plasmacytic differentiation was observed, however, in this culture system.

Metabolically, no distinction could be made between cells undergoing blastogenesis with the extracts from the seeds of *Wistaria* and those responding to pokeweed mitogen or to phytohaemagglutinin. We have recently published a detailed description of the histochemical properties of lymphocytes responding to these mitogens<sup>3</sup>. Acid phosphatase and  $\beta$ -glucuronidase activities were prominent in preblastic lymphocytes; lipid vacuoles were abundant in cells undergoing blastogenesis; glycogen was markedly increased in the responding cells, but rarely present in frank blasts. No  $\alpha$ -amylase stable periodic acid-Schiff positivity was observed during the 72 h culture period. Lymphocytes were never reactive for alkaline phosphatase.

Like *Phaseolus vulgaris*, *Wistaria* is a member of the family Leguminosae, subfamily Papilionoidae. This subfamily is comprised of a very large number of widely distributed genera displaying diverse characteristics. The family Phytolaccaceae, to which pokeweed (*Phytolacca americana*) belongs, is generically widely separated from the Leguminosae. Börjeson and his colleagues have recently isolated and characterized the pokeweed mitogen<sup>4</sup>, but the relationship of this substance to the mitogens of *Phaseolus* and *Wistaria* remains unresolved.

### Induction of Mitotic Recombination in *Saccharomyces cerevisiae* by Ethyl Methane Sulphonate

MITOTIC recombination can be induced in *Saccharomyces cerevisiae* by exposing them to ultra-violet and X-radiation<sup>1</sup>. The genetic maps so obtained closely parallel those from meiotic recombination<sup>2</sup>. One of the most useful features of mitotic recombination is that it is relatively easy to observe intracistronic recombination. It is possible that this results from a mechanism somewhat different from that leading to meiotic recombination characteristic of higher organisms. For this reason, we decided to study the effects of certain chemical mutagens on the process of mitotic recombination in the hope of being able ultimately to compare these results with those obtained in more usual systems.

For our initial investigations we chose to work with the alkylating agent ethyl methane sulphonate (EMS). This

agent is known to act as a point mutagen, largely through the alkylation of the guanine residue of DNA (ref. 3). As a point mutagen, EMS produces a very low level of chromosome breakage<sup>4</sup>, and thus it was expected that it might be used to provide a test of the breakage and reunion hypothesis of recombination. This idea was reinforced by the report of Morpurgo that monofunctional alkylating agents were not effective in the induction of mitotic recombination in *Aspergillus*<sup>5</sup>. We assumed that a true "point" mutagen would not increase recombination if chromosome breakage were the initiating event and that a deleting agent would. Since we started these experiments, it has been reported that diethyl sulphate will induce mitotic recombination<sup>6</sup>. It is therefore not surprising to find that the results of the experiments reported here indicate that our initial assumption was incorrect, because EMS can dramatically increase recombination.

For these investigations we used mutant strains of the two alternate mating types ( $a$  and  $\alpha$ ) requiring tryptophan ( $tr$ ), uracil ( $ur$ ) or histidine ( $hi$ ). Mutations in the  $hi_5$  and  $hi_4$  cistrons were induced by EMS in  $tr a$  haploid strains, and these were subsequently crossed to either  $ur_1 hi_5 \alpha$  or  $ur_1 hi_4 \alpha$  strains to form the diploids. To facilitate identification the original  $\alpha$  strains were designated  $hi_{5a}$  and  $hi_{4a}$ , and the newly obtained mutants were given other designations ( $hi_{5b}$ ,  $hi_{5c}$ , etc.). We carried out tests of spontaneous recombination with the  $hi_{5a}$  and  $hi_{4a}$  strains, and obtained the relative map distances from the  $hi_a$  mutants<sup>7</sup>. Because EMS induced large increases in recombination frequency, diploids showing relatively low frequencies of spontaneous recombination were selected for use in the experiment.

We treated diploids, freshly generated for each test, with 3 per cent EMS in phosphate buffer, for varying periods of time. After treatment, the cells were spun down and washed twice with 6 per cent sodium thiosulphate and once with distilled water before plating them on minimal medium. We made cell counts by plating aliquots on complete medium. The untreated cells were subjected to all procedures other than the addition of EMS. All treatments and incubations were carried out at 30° C. In all cases, growth was allowed to proceed for 72 h in order to permit the maximum number of recombinants to arise. (Treatment with EMS greatly slows the growth.)

Because only recombinants will grow on the minimal medium, the scoring is relatively simple<sup>1</sup>. On the other hand, only cells wild-type for histidine will grow. Any reciprocal recombination event that produces a doubly mutant individual could not be detected in these tests, and thus there is no indication of the exact nature of the recombination process.

As a test for reversion, homoallelic diploids (having the locus of mutation at the same place on both chromosomes) were used. These were treated in exactly the same manner as were the heteroallelic diploids. Because the homoallelic diploids cannot recombine, it is to be presumed that they offer a satisfactory estimate of the diploid revertants. In addition, reversion of the haploid strains from which one of the diploids was generated was measured.

In each experiment, at least fifteen plates were scored for each treatment, and all experiments were repeated at least three times. The data in Tables 1 and 2 and the points in Fig. 1 are all mean values from these experiments. There is some variability in the data, but it can be accounted for by variations in the initial cell number in each experiment. Doubling the cell number obviously halves the concentration of EMS in the cells, and results in a comparable decrease in recombination frequency. This can be seen by comparing the results obtained with a treatment for 35 min (Table 1) with those presented in Fig. 1. (The data in Fig. 1 were obtained at higher initial cell numbers.)

The data in Table 1 show that EMS causes a drastic rise in the frequency of recombination of relatively closely linked mutational sites in the  $hi_5$  cistron. It can be

Table 1. MEAN NUMBER ( $\times 10^{-3}$ ) OF REVERTANTS AND RECOMBINANTS OF TWO MUTATIONAL SITES WITHIN THE  $hi_3$  CISTRON

Cells treated		Treatment (min)		
		0	20	35
HE	$hi_{3a}/hi_{3b}$	49	177	276
HO	$hi_{3a}/hi_{3a}$	0.1	0.3	0.6
HO	$hi_{3b}/hi_{3a}$	0.1	0.2	0.5
H-a	$hi_{3a}$	1	4	10
H-a	$hi_{3a}$	0.1	1.0	2.0

Symbols are as follows: HE, heteroallelic diploid; HO, homoallelic diploid; H-a, haploid  $a$  strain; H-a, haploid  $a$  strain.

Table 2. MEAN NUMBER ( $\times 10^{-6}$ ) OF REVERTANTS AND RECOMBINANTS OF TWO CLOSELY LINKED MUTATIONAL SITES WITHIN THE  $hi_4$  CISTRON

Cells treated		Treatment (min)			
		0	10	20	30
HE	$hi_{4a}/hi_{4b}$	6	44	81	95
HO	$hi_{4a}/hi_{4a}$	0.1	0.3	0.7	1.0

Symbols are as follows: HE, heteroallelic diploid; HO, homoallelic diploid.

seen that the recombination in the heteroallelic diploid is far in excess of the reversions found in either the haploid or homoallelic diploid strains.

Table 2 suggests that the same effect can be observed in the  $hi_4$  cistron, in which two more closely linked mutational sites were utilized. It should be noted that at the longest treatment time, the  $hi_4$  recombination shows a non-linearity. On the other hand, as indicated in Table 1 and in Fig. 1, for the  $hi_3$  cistron the response to treatment is apparently linear.

The data in Fig. 1 were obtained using a higher initial cell number (and thus giving a lower kill) than used to obtain the data in Table 1. Furthermore, in Fig. 1 the reversion frequency of the homoallelic diploid is subtracted from the total number of recovered clones, and thus the data are frequencies of recombination. It can be seen that, under these conditions, the response is essentially linear over a relatively wide range of treatment times.

It is evident that, although it is a monofunctional alkylating agent, EMS can strongly affect intracistronic recombination in *S. cerevisiae*. Thus it would appear that EMS will not be useful as a "control" for the test of the breakage and reunion hypothesis of genetic exchange. The data presented here are consistent with the model proposed by Holliday<sup>9</sup>, which suggests that any defect arising in the DNA may result in a repair process leading to genetic exchange. Preliminary tests carried out on meiotic recombination in *Drosophila* indicate that EMS is effective in increasing genetic exchange in certain regions. This fact taken with the data presented in this com-

Fig. 1. Variation in recombination of two mutational sites within the  $hi_3$  cistron with time of exposure to EMS. Corrected for reversion. The number killed is half that for the experiments summarized in Table 1.

munication makes it reasonable to suggest that the mechanism of production of genetic recombination is different from that responsible for the production of chromosomal aberration.

Perhaps the most interesting feature of these data is linear response shown to EMS treatment time (and probably to dose, comparing the data in Table 1 and Fig. 1). Thus EMS apparently acts in much the same manner as X-rays but unlike that of ultra-violet light. It will be interesting to continue these investigations to determine whether or not the slope of the curve can be used to map mutants, as can X-rays<sup>1</sup>.

The authors are greatly indebted to Dr Gerald Fink, of the US National Institutes of Health, who provided some of the original strains used in this experiment and was generous in his advice. The work was supported, in part, by a grant from the National Institutes of Health.

## GENETICS

### New Genotypes in Cod at Greenland

THE blood sera of cod (*Gadus morrhua* L.) show certain protein types which were believed to be inherited. Møller<sup>1</sup> tested blood samples from cod caught along the Norwegian coast and in the Barents Sea, and described eleven molecular patterns of iron-binding proteins, or transferrins. Ten of the observed patterns represented all the possible genotypes attributable to four co-dominant allelomorphous genes  $TfA$ ,  $TfB$ ,  $TfC$  and  $TfD$ , each controlling one of four proteins. Gel electrophoresis revealed each protein as a discrete band. The alphabetical order of the gene suffixes followed the decreasing order of their electrophoretic mobility. Møller's remaining type of pattern contained a rare protein with an intermediate mobility faster than that of the protein attributed to the commonest allelomorph  $TfC$ , and he proposed a new allelomorph  $TfC^1$ . Møller found six examples of  $TfC^1/TfC$ , and his genetic interpretation anticipated the existence of the genotypes  $TfA/TfC^1$ ,  $TfB/TfC^1$ ,  $TfC^1/TfC^1$  and  $TfC^1/TfD$ . Numerous examples of each of these anticipated genotypes have in fact been discovered in the blood sera of West Greenland cod, and are presented here for the first time.

The testing methods and the notation of the cod transferrins were those of Møller<sup>1</sup>, who kindly provided me with control sera which allowed the identities of the four more familiar proteins to be equated in the tests made in Bergen and Lowestoft.

Fig. 1 shows all five genotypes containing the gene  $TfC^1$  as it appeared in the course of routine tests of unknown sera. Each unknown was tested alongside an established control serum of genotype  $TfB/TfC$ , the most frequently encountered two-band transferrin pattern in cod. Fig. 2 is a diagram based on the photograph and shows the rare genotype patterns as solid lines and the control pattern as broken lines.

The 708 cod sampled at West Greenland showed the following gene frequencies, with their standard errors:

Allelomorph	$Tf^A$	$Tf^B$	$Tf^{C1}$	$Tf^C$	$Tf^D$
Gene frequency	0.129	0.227	0.035	0.524	0.085
Standard error	$\pm 0.009$	$\pm 0.011$	$\pm 0.005$	$\pm 0.013$	$\pm 0.007$

The results of these and previous tests suggest that the order of magnitude of the frequencies of the five cod transferrin genes is consistently  $Tf^C > Tf^B > Tf^A > Tf^D > Tf^{C1}$  throughout the distribution of this species in the North Atlantic Ocean. The West Greenland sample shows the lowest known frequency of  $Tf^C$ , together with the highest known frequencies of  $Tf^A$ ,  $Tf^B$ ,  $Tf^D$  and  $Tf^{C1}$ .

Table 1. THE FIFTEEN TRANSFERRIN GENOTYPES IN 708 COD AT WEST GREENLAND

Genotypes	Observed	Expected	
$Tf^A/Tf^A$	13	12	
$Tf^B/Tf^B$	52	37	
$Tf^{C1}/Tf^{C1}$	4	1	New type
$Tf^C/Tf^C$	227	194	
$Tf^D/Tf^D$	12	5	
All homozygotes	308	249	
$Tf^A/Tf^B$	30	41	
$Tf^A/Tf^{C1}$	7	6	New type
$Tf^A/Tf^C$	100	95	
$Tf^A/Tf^D$	19	15	
$Tf^B/Tf^{C1}$	11	11	New type
$Tf^B/Tf^C$	144	169	
$Tf^B/Tf^D$	33	27	
$Tf^{C1}/Tf^C$	12	23	
$Tf^{C1}/Tf^D$	12	4	New type
$Tf^C/Tf^D$	32	63	
All heterozygotes	400	459	

The observed numbers of transferrin types in cod caught between Disko Bay and Cape Farewell in October 1966 are shown in Table 1. When a Hardy-Weinberg test is applied to this material the very significant departures from numerical expectations indicate that this is a composite sample of two or more genetically isolated stocks. More detailed analyses of the genetic structure of cod stocks at Greenland and elsewhere in the North Atlantic will be published in due course. It is increasingly apparent that this genetic diversity in cod can be used to estimate the degrees of isolation of the various breeding stocks. This knowledge can be applied to stock conservation problems and in the routine classification of fishery statistics.

## BIOLOGY

### Facultative Autogeny in Arctic Mosquitoes

OVARIAN development in the mosquitoes *Aedes (Ochlerotatus) impiger* (Walk.) and *A. (O.) nigripes* (Zett.) has been studied at Hazen Camp, northern Ellesmere Island (71° 18' W., 81° 49' N.), a site only 150 miles south of the northernmost limit of land. Both species seek blood actively and, if able to engorge, use it to mature eggs in the usual way. A factor thought to limit their reproductive success is the low availability of blood, resulting from the scarcity of vertebrates and the prevalence of weather inimical to host-seeking during the brief flying season of the mosquitoes.

Experiments in 1963 showed that some females of both species show autogeny; that is, they complete ovarian development (the follicles reaching the fifth stage of Christophers<sup>1</sup>) without a blood-meal. During autogenous ovarian development many follicles degenerate and thus fecundity is greatly reduced<sup>2</sup>. Autogeny is found in the first ovarian cycle in several genera of mosquitoes, and in some species both autogenous and anautogenous (blood-feeding) members occur. In these the course of ovarian development is assumed to be predetermined, at the time of emergence, on one course or the other, although so far this has been confirmed only for *Culex pipiens* variety *molestus* Forsk<sup>3</sup>. This type of autogeny may be termed obligate. The 1963 experiments at Hazen Camp, however, suggested that, in some females at least, autogeny during the first cycle is facultative—individuals can mature eggs with or without blood, depending on circumstances. Such a condition had not previously been demonstrated in mosquitoes, but we have confirmed its existence in these two Arctic species. This has posed the further question of when the switch from potentially anautogenous to autogenous development occurs; at this transition a female exchanges the chance of being able to lay many eggs for the near certainty of being able to lay a few.

Experiments at Hazen Camp in 1966 helped to answer this question. Female mosquitoes (a total of about 320) of both species were collected either as nulliparous adults (those that have not yet laid eggs) attempting to bite in the wild when about 3 days old (Table 1, "attracted"), or as pupae that were allowed to emerge in captivity ("reared"). They were confined individually with con-

Fig. 1. Selected examples of the results of routine electrophoretic tests which separate the soluble proteins in cod sera. The proteins appear as stained bands on the anodic side of gels supported on five microscope slides measuring 3 in.  $\times$  1 in. Each slide shows the protein components of two sera. Five labelled examples of the uncommon cod transferrin genotypes  $Tf^A/Tf^{C1}$ ,  $Tf^B/Tf^{C1}$ ,  $Tf^{C1}/Tf^{C1}$ ,  $Tf^{C1}/Tf^C$  and  $Tf^{C1}/Tf^D$  were tested in parallel with a control serum of genotype  $Tf^B/Tf^C$ .

Fig. 2. Diagram outlining the transferrin band patterns seen in the photograph. Certain additional variable proteins seen in the photograph are not relevant. Note the positions of the five cod transferrin bands which are represented in the diagram by solid lines. The control genotype is represented by broken lines.

Table 1. SIZES OF BATCHES OF EGGS IN NULLIPAROUS MOSQUITOES THAT COMPLETED OVARIAN DEVELOPMENT

Category (in order of declining fecundity)	<i>Aedes impiger</i>			<i>Aedes nigripes</i>		
	Median	Range	No. of mosquitoes	Median	Range	No. of mosquitoes
(A) Potential complement (follicles at emergence)	53	(34-71)	16	52	(34-78)	44
Anautogenous (offered blood; engorged)						
(B) Attracted	53	(25-78)	21	39	(22-62)	14
(C) Reared	34	(22-52)	16	31	(24-41)	14
Autogenous (denied blood)						
(D) Reared; obligate	6	(4-8)	2	25	(21-31)	5
(E) Attracted; facultative	6	(2-10)	13	2	(1-5)	3
(F) Reared; facultative	3	(1-7)	6	3	(1-4)	5

Except for (A) all references are to mature eggs.

tinuous access to 25 per cent sucrose solution and two flowers (renewed daily) of *Dryas integrifolia* Vahl., their usual source of nectar. Human blood was offered or withheld according to various regimes; females biting were allowed to engorge and were not offered blood again. Results reported here refer only to the first ovarian cycle and, unless otherwise specified, to both species.

Most females (and probably all females of *A. impiger*) can mature eggs without a blood-meal. In the great majority this autogeny is facultative, but in some it is obligate.

Females exhibiting facultative autogeny, if not allowed to blood-feed, remain for about 10 days with the ovaries in a state of suspended development (the third and fourth stages of Christophers) and then start to mature eggs autogenously: a few follicles enlarge while the rest degenerate until, about 10 days later, a very small number of eggs has matured (Table 1, E, F). By this time a female is about 20 days old. During their first 10 days, however, females readily take blood (maximum on days 2-4), and if they do feed a large batch of eggs matures (Table 1, B, C). The transition from potentially anautogenous to autogenous development probably reflects a female's energy reserves, and so the age at which it occurs can be expected to be somewhat different in the wild, and to vary from year to year according to the extent to which weather permits feeding on nectar.

Females exhibiting obligate autogeny begin to mature eggs promptly after emergence, and are ready to lay them about 10 days later. In *A. impiger* the number of eggs matured is markedly less than in females that obtain blood; in *A. nigripes* it is slightly so (Table 1, D). Females showing obligate autogeny do not normally seek blood (as nullipars) in the wild, an inference based on their absence from baited catches. Nevertheless the behaviour of captive females shows that some at least retain the ability to bite and engorge. So presumably, as in other mosquitoes<sup>5</sup>, and certain blackflies<sup>6</sup>, that exhibit autogeny, females need blood to begin the second ovarian cycle.

These results show that these two Arctic species are more flexible in their ovarian maturation than any other mosquitoes so far examined. This versatility can be seen as appropriate to survival in the exceptionally severe and variable environment in which they live.

## A *Neopilina* from the Gulf of Aden

On February 22, 1967, R.R.S. Discovery, of the National Institute of Oceanography, dredged a single specimen of the monoplacophoran mollusc *Neopilina* in the Gulf of Aden. This specimen (Figs. 1-3) represents the first record of the genus beyond the depths of the eastern Pacific. First collected in 1952 off Costa Rica, and reported by Lemche<sup>1</sup>, *Neopilina* is representative of a group previously considered extinct since Devonian times. Up to 1960 it had also been found off northern Peru and Baja California, but no further reports have since been noted and the Discovery record is an indication of much wider distribution than could previously be contemplated.

It will be recalled that *Neopilina* displays segmental characters which may be homologized with those present in some annelids and arthropods, previously unknown in molluscs. It is as an indication of a form adopted in the evolution of the ancestors of this very successful marine invertebrate group, the Mollusca, that *Neopilina* is of interest.

The Discovery specimen (described here as a new species) has five pairs of gills (Fig. 3) and in this feature is much closer to the species described as *Neopilina galathea* (ref. 1), and *Neopilina veleronis* (ref. 2), from off Baja California, than to *Neopilina ewingi*, which has six pairs, from off Peru (ref. 3). In *N. galathea* the apex of the shell is almost immediately over the front margin, in *N. veleronis* it is in advance of the front margin, whereas in the present specimen it is set back from this margin (Fig. 1).

*Neopilina adenensis* n.sp. Figs. 1, 2 and 3.

**Type locality:** The Alula-Fartak trench in the Gulf of Aden, 13° 50' N., 51° 47' E., between 3,950 and 3,000 m: R.R.S. Discovery St. 6213.

**Holotype.** B.M.(N.H.) Reg. No. 19672 W.

The holotype measures 10.7 mm in length by 10.1 mm wide; the shell is convex with a maximum depth of about 3.0 mm; the hooked apex of the shell is situated about 0.8 mm from its front margin. The shell is white near its margin, tending to light brown elsewhere; its surface is sculptured with numerous concentric ridges numbering about seventy-five up to the apical region where they run too close together to be counted; in the central region the concentric sculpture becomes irregular, being interspersed with discontinuous grooves of varying depths; faint radiating sculpture occurs in the margin area and towards

Fig. 1. *Neopilina adenensis* n.sp.; dorsal view of the holotype, which measures 10.7 mm across its longest dimension.

the centre. In ventral view the body of the animal is exposed; it has five pairs of gills, a set of five being disposed in series in the pallial groove on each side of the foot; each gill has six or seven branches running off one side of a main stem. The postoral tentacles are branched.

The sample was collected by Dr J. R. Cann of the Department of Mineralogy, British Museum (Natural

History), during investigations of the structure and origin of the Gulf of Aden by a marine geological group led by Dr A. S. Loughton of the National Institute of Oceanography.

### Standardization of *Bacillus thuringiensis* Products: Homology of the Standard

THE lethality of *Bacillus thuringiensis* to many lepidopterous larvae has led to its development as a "biological insecticide". Products based on this bacterium contain two active ingredients, the spore and the crystal of toxic protein, and sometimes a third, the exotoxin. The water-soluble exotoxin is secreted into the medium during vegetative growth and the crystal is formed alongside the spore at sporulation. Because the crystal is by far the most important ingredient against many Lepidoptera and cannot be estimated chemically, the realization that the insecticidal activities of different preparations cannot be consistently measured by counting the spores was an important advance in the problem of standardization. Bioassay, with species of insect sensitive only to the crystal, is taking the place of the spore count. The recent adoption of one batch of stable bacterial preparation, E61, as the international standard has provided both a recognized material with which other materials can be compared and a basis for establishing toxicity units. Such measurement of the crystal content of materials should work well with products containing the same strain of bacterium as the standard, that is, when the standard is homologous.

The use of a standard, however, has its pitfalls. The standard can be regarded as only partially homologous with products containing other strains of the bacterium. Different species of assay insect may give very different comparative toxicity values between bacterial products if the susceptibilities of the different insect species to the various bacterial strains are unlike. This is illustrated by the example in Table 1. The insecticidal activity of the standard has been designated arbitrarily as 1,000 units/mg. In *Anagasta* units, the product S is 10.6 times as active as 'Bakthane', but in *Galleria* units it is 76.3 times as active. This is explained by the different susceptibilities of the two species of insect to the two strains of bacteria. The  $LD_{50}$  values of the present assays, and assays of other bacterial preparations containing these strains of bacteria, show that *Anagasta* has similar susceptibilities to the two strains but that *Galleria* is much more susceptible to strain *galleriae* than to strain *thuringiensis*. Similar relationships exist between other pairs of bacterial strains and host insects.

Thus, when the standard is incompletely homologous, it is impossible to rely on units based on only one species of assay insect in measuring the insecticidal activity of

crystals in different products. At best, one can group species of pest insects according to their susceptibilities to different bacterial strains and use the most convenient assay insect in each group to provide a unit for its group.

Alternatively, one could erect a separate international standard for each bacterial strain. This is less satisfactory, not only because it would greatly increase the number of available units, leading to severe complication, but also because the characters of the existing strains can be and are being manipulated to increase productivity, etc., and a "manipulated" strain would probably not be homologous with any one of the known natural strains.

These considerations emphasize the need for fundamental study of the toxic action of the crystal of different strains of *B. thuringiensis* in different species of insect. Analogous difficulties are likely to arise in all attempts to standardize pathogens, bacterial or otherwise, active against more than one species.

### Pentamerism and the Calcite Skeleton in Echinoderms

COCKBAIN<sup>1</sup> has suggested an extension of the suture-line theory<sup>2</sup> of the origin and significance of pentamerism in the phylum Echinodermata, which depends primarily on the fact that all modern echinoderms with extensive skeleton apparently pass through a stage in which the apical system or calyx shows a common arrangement of six plates: a central plate surrounded by a whorl of five. The apical system is of chief importance in establishing the symmetry of the rest of the body. Because the apical system of the young echinoderm occupies a large part, if not all, of one face or pole of the body, the places of greatest weakness in that area of plates (the sutures between them) must be so arranged that: first, they are kept as few and as short as possible; second, that no suture should be directly in line with any other; and, third, that this first whorl of the theca should be as nearly circular as possible. Only with a pentamerous arrangement are these requirements satisfied.

Although Cockbain accepts the main premises of this theory, he seeks to link pentamerism with another unique feature of the phylum—the possession of skeletal elements apparently composed of single crystals—and considers that previous theories have not suggested adequate reasons why five-fold symmetry has an advantage over three-fold for this group of animals. His principal point is that the angle between the faces of the cleavage rhomb of the calcite crystal is about 75°, which is sufficiently close to the angle between five equally spaced radii of a circle (72°) to account for the superiority of pentamerism. A further point is that with this arrangement only two cleavage directions will cut across each plate, reducing the chance of breakage.

If Cockbain's idea is correct, the initial ring of plates should be oriented in such a way that the crystallographic c-axis leaves each plate at the same angle relative to the plane of the plate surface and to the oral-aboral axis of the animal. But this is apparently not so. It has been shown<sup>3</sup> that the c-axis orientation of the genital plates of most echinoids (the only class of echinoderms that has been adequately studied in this respect) departs from perfect radial symmetry: genital plates *G*-1, *G*-2 and *G*-4 (on Lövén's<sup>4</sup> scheme of plate notation, in which *G*-2 is the madreporite) have c-axes perpendicular to the plate

surface, while plates *G*-3 and *G*-5 have axes tangential to it.

It seems therefore that the premise on which Cockbain bases his extension of the suture-line theory of echinoderm pentamerism must in some respects be wrong, if only in the case of echinoids. That there may well be some connexion between the possession by this phylum of a unique type of skeleton<sup>5</sup> and an almost unique type of symmetry has already been suggested<sup>2</sup>, but only in so far as the great strength of the skeletal material emphasizes the relative weakness of the sutures between the skeletal elements.

Fell<sup>6</sup> has pointed out that the larvae of all comatulid crinoids, ophiuroids and asteroids for which the development is known have apical systems consisting of the familiar pattern of five plates surrounding a central plate. This pattern occurs transiently in those forms in which the plating of the disk region subsequently becomes randomized; it occurs in ophiuroids in which the adult disk is completely naked; it even occurs in those forms in which the adult animal secondarily loses pentamerism, as in the Antarctic comatulid *Promachocrinus*<sup>6</sup>. Thus because there appears to be a common pentamerous symmetry in the apical or calycinal plates, albeit briefly, for some time during the immediately post-larval life of so many echinoderms, it seems reasonable to seek the importance of its arrangement at this time in the life of the animal.

The suture-line theory gains cogency from the fact that, when the developing skeletal system of the young echinoderm is relatively weakly interconnected, the apical system may occupy most of its dorsal (aboral) surface (see, for example, ref. 6, Fig. 15, Nos. 6, 9 and 12; ref. 7, Fig. 17 and p. 287; and ref. 8, Plate II, Fig. 4, and Plate IV, Fig. 3).

One possible criticism of the theory lies in its incapacity, at first sight, to explain the advantage of five-fold over three-fold symmetry. In both, a linear projection from the radial suture between two adjacent plates exactly bisects the opposite plate; it is not in line with another suture, as would be the case in tetramerous, hexamerous or any other even number symmetry. Furthermore, the trimerous condition shows two possible advantages: first, there is a sharper angle between the radial sutures on opposite sides of the apical disk than in the pentamerous arrangement (120° as opposed to 144°) and, second, there are fewer suture lines in the complex of plates of the apical disk, which implies fewer lines of weakness. The explanation for the superiority of pentamerism appears to lie in the advantage of having a theca which approaches a circular cross-section without undue deformation or strain to the crystals of the plates; it may well be that an initial whorl of five plates and subsequent whorls of five, or, in some, multiples of five derived from this, is the lowest number that can achieve such a shape while still fulfilling the other requirements of the initial whorl at the critical stage in ontogeny.

The sparse literature on the attributes and significance of pentamerous symmetry has been reviewed elsewhere<sup>9</sup>. Bather's<sup>10</sup> suggestion that the condition arose from an original trimerous symmetry by subdivision of the two lateral radii has been re-stated by Fell<sup>11</sup>. This idea is at first sight attractive, because there is fossil evidence of trimerous symmetry in some edrioasteroids and cystoids; further, edrioasteroids are among the first echinoderms to appear in the fossil record<sup>12</sup>, and some authors<sup>10</sup> regard cystoids as among the most primitive echinoderms, on morphological grounds. Interesting though it is in underlining the theoretical similarity of the trimerous and pentamerous conditions, this idea does little to explain why the pentamerous condition has persisted so tenaciously throughout the history of the phylum, even when the way of life of its members shows such variety. Moreover, if there is advantage to be gained merely from subdividing the two lateral radii of the original three, it is not

easy to see why in the vast majority of echinoderms the process has stopped on attaining five.

In spite of many difficulties in the suture-line theory, particularly the impracticality of demonstrating experimentally its main premise, it remains attractive because it helps to account for so many otherwise strange phenomena of development. But the fact remains, as Cockbain<sup>1</sup> has pointed out, that any theory of echinoderm pentamerism which could be more closely linked with other unique features of the phylum, such as the single-crystalline condition and open-meshwork nature of the skeleton<sup>5</sup>, would be highly attractive; such a theory must, however, be consistent with the facts.

### Stimulation of Hatching of the Potato-root Eelworm *Heterodera rostochiensis* by Ion Exchange Resins

We have already reported the possibility that de-ionized water might stimulate hatching of the potato-root eelworm<sup>1</sup>. We now present confirmatory evidence: glass distilled water which has been in contact with certain ion exchange resins acquires marked stimulatory properties.

10 g of standard grade 'Amberlite IRA 400' resin was thoroughly stirred up in 100 ml. of glass distilled water and then allowed to stand for 24 h. The decanted supernatant constituted solution A, of unknown composition. In a hatching test of four weeks duration, using dilutions A, A/2, A/4, A/8, A/16, A/50, each tested on twenty-five cysts with a single cyst technique<sup>2</sup>, mean larval emergence per cyst was 263, 111, 209, 250, 262 and 102, respectively. Emergence from 100 cysts in tap-water was 8 per cyst. The "resin water" was therefore very powerful; in an almost concurrent experiment with cysts from the same population, emergence in solutions of a hatching factor concentrate known to be of high activity was about 150 per cyst.

In a repeat experiment which included a series of dilutions of the hatching factor concentrate, emergence was somewhat lower in the resin water. 160 larvae per cyst emerged in the most active of the hatching concentrate solutions, and 97 in the most active resin water. An analysis of variance was carried out with a logarithmic transformation because of the skew nature of the data<sup>3</sup>. Values of  $\log(x+1)$  were used, where  $x$  is the number of larvae to emerge per cyst. Emergence in all dilutions of resin water was significantly greater than in the water controls; the highest values did not differ significantly from the emergence in all but the two most concentrated of the hatching factor solutions.

First experiments show that a number of other resins possess the property. Clearly, de-ionized water must be used with circumspection in hatching tests. Moreover, the use of ion exchange resins, even after exhaustive pretreatment, in procedures directed towards the isolation of

the hatching factor, must be attended by some risk, particularly where recovery rates are on the low side. The nature of the substance, or substances, involved is under investigation.

We are grateful to Dr G. J. Janzen, of Groningen, for the hatching concentrate, and to Mrs A. Stephenson for her assistance.

### Attempt to find Genetic Recombination in *Anacystis nidulans*

GENETIC relationships in the blue green algae (Cyanophyceae or Myxophyceae) are still obscure. There is some similarity between the nucleoplasmic ultrastructure of blue green algae and that of bacteria<sup>1</sup>, and this similarity might also apply to the genetic processes of these two organisms, but there are no data for or against this idea. Kumar assumed that there was one case of a sexual or parasexual process in *Anacystis nidulans*<sup>2</sup>. We have carried out experiments with this organism similar to those of Kumar, and the results are discussed in this communication.

The Cambridge strain of a strictly autotrophic, mild thermophilic, unicellular blue green alga, *Anacystis nidulans* (from the Collection of Cultures of Autotrophic Organisms, Czechoslovak Academy of Sciences in Prague), was cultured in a slight modification of the liquid basal medium C of Kratz and Myers<sup>3</sup> at 39° C and 1,700 lux on a shaker. This strain was unable to form discrete colonies on agar-agar plates. The standard culture was first tested for sensitivity to ten different chemotherapeutic drugs (see Table 1) and then it was cultured in media supplemented with gradually increasing concentrations of the respective drugs. By this procedure we obtained strains surviving in penicillin, streptomycin and isonicotinhydrazide which were 15, 100 and 200 times more concentrated. The sensitivity to the other chemotherapeutic drugs did not change markedly during ten transfers of the standard strain in the drug supplemented media, as Table 1 shows.

Table 1. SENSITIVITY OF *Anacystis nidulans* TO CHEMOTHERAPEUTIC DRUGS

Drug	Original level of resistance ( $\mu\text{g/ml}$ or IU/ml.)	Final level of resistance	Mode of origin of resistance
<i>p</i> -Aminosalicylate	This drug has no effect even in concentrations of about 1,000 $\mu\text{g/ml}$ .		
Chloramphenicol	1	3	In one step
Cycloserine	10	No increase	—
Isonicotinhydrazide	10	150	In seven steps
Neomycin	0.1	No increase	—
Penicillin	0.1	10	In five steps
Streptomycin	1	200	In seven steps
Tetracycline	1	No increase	—
Vancomycin	50	No increase	—
Viomycin	0.1	No increase	—

The increase of resistance in all three successful cases occurred in several stages; this differs substantially from the analogous processes known in bacteria<sup>4</sup> and could indicate a different kind of genetic control of resistance to the respective drugs in blue green algae.

The strains resistant to penicillin (*PEN<sup>r</sup>*) and to streptomycin (*STR<sup>r</sup>*) were used in an attempt to find genetic recombination. Both strains were tested first for stability of drug resistance by ten successive transfers through basal medium, when no decrease of resistance was observed. Also the cross-resistance to both antibiotic

was tested and found to be negative. Basal medium containing no antibiotics was then inoculated simultaneously into a culture consisting of cells of *PEN<sup>r</sup>* and *STR<sup>r</sup>* strains. Samples were withdrawn from this mixed culture at various times and were transferred into selective medium supplemented with both penicillin (10 IU/ml.) and streptomycin (200 µg/ml.). Growth was observed in seven out of thirty-two culture-flasks in four independent experiments. These "recombinant" cultures, however, did not grow in further transfers in medium containing both drugs or even penicillin only, but it occurred in medium supplemented with streptomycin only or in medium without antibiotics. These observations support the idea that the supposed recombinant cultures are only members of the *STR<sup>r</sup>* strain which have survived contact with penicillin.

This explanation is based on the fact that all seven positive results were obtained only with samples taken from the stationary growth phase of the mixed culture. Considering the similar chemical composition of cell walls of *Anacystis nidulans* and of Gram positive bacteria<sup>1</sup> we can suppose that similar mechanisms of inactivation by penicillin are at work in each case. The cells of inocula withdrawn from the stationary growth phase remain in selective medium for about 6 or 7 days in the metabolic lag phase and that is why they survive in the presence of penicillin. Using the modified Hildick-Smith-Fell micromethod<sup>6</sup> we found that by the sixth day of culture there was no penicillin left in the medium, so that any cells of the strain *STR<sup>r</sup>* which survived the lag could start to grow regularly. In control experiments the medium containing penicillin only was separately inoculated with cells of strain *STR<sup>r</sup>* and also of the standard strain; inocula were withdrawn from the stationary growth phase of the cultures, and in all cases there was growth in medium supplemented with penicillin.

Kumar's idea of the existence of a sexual or parasexual phenomenon in *Anacystis nidulans*<sup>2</sup> was based only on the fact that the growth of the mixed culture of penicillin- and streptomycin-resistant strains (each of them only ten times more resistant than the standard strain) was observed in the medium supplemented with both respective drugs. Our results suggest that the observed growth of the mixed culture in the given selective medium is dependent on the presence of non-metabolizing (and therefore surviving contact with penicillin) cells of strain *STR<sup>r</sup>* in the appropriate inoculum. We assume that the ability of the mixed culture to grow in the given selective medium does not in this case sufficiently demonstrate sexual or parasexual recombination in the blue green alga.

I thank Dr Jan Nečásek for his advice.

### Accumulation of Copper by Some Zambian Plants

In the areas of Zambia which are rich in minerals there are several species of plants which are both accumulators and geo-botanical indicators of copper. The relation of these plants to soil copper has been surveyed in the initial stage of an investigation of the effects of heavy metals on the metabolism of plant cells. The survey was conducted

mainly in some of the typical "copper clearings", areas in which the soil is rich in copper and where normal bush vegetation is replaced by copper-resistant species.

Soil samples from a number of non-mineralized areas of Zambia contained between 17 and 65 p.p.m. (total) copper. Plants growing on such soils do not accumulate copper to any significant extent. The situation is quite different in mineralized areas.

A wide range of plants, both from mineralized and non-mineralized areas, were collected and analysed for copper. A wet ashing procedure was followed by analysis on a Unicam 'SP900A' atomic absorption spectrophotometer. Several species were found to tolerate a large concentration of soil copper and to accumulate a relatively large concentration of the metal in their leaves. Among these are some "indicator" plants, *Becium homblei*, *Vernonia glaberrima*, *Triumfetta welwitschii* and *Cryptosepalum maraviense*. These are all small herbs or shrubs with woody rootstocks. Some species of Graminae were found to grow on soils rich in copper, but did not accumulate the metal. A specimen of *Trachypogon spicatus*, on soil containing 7,250 p.p.m. of copper, had only 15 p.p.m. of copper in its leaves. Besides these copper accumulators and copper-resistant species were a number of less selective plants, which, while tolerating in certain areas considerably more than a trace of soil copper, usually prefer non-mineralized areas. These include several woody shrubs and small trees such as various species of *Combretum* and *Pterocarpus angolensis*. Many species are cuprifuge and are not found on soils containing more than 20-40 p.p.m. of copper. Two of these, *Becium obovatum* and *B. angustifolium*, are interesting because they are closely related to the copper accumulator, *B. homblei*.

Cell juice was pressed from two species of *Becium* and the *B. homblei* had 0.092 mmolar copper ions, while *B. obovatum* had 0.05 mmolar copper ions. The total copper content for the specimens was for *B. homblei* 65 p.p.m. dry, or 16 p.p.m. fresh weight, and for *B. obovatum* 6 p.p.m. dry, or 1 p.p.m. fresh weight. These results suggest the *B. homblei* can remove copper from free solution in its cell sap, possibly by binding it as a complex with protein.

The results of a study of accumulation of copper by *B. homblei* in different soil conditions are summarized in Table 1. It is seen that, in general, a large concentration of soil copper leads to a large accumulation by the plants. It should be noted that the Allies and Chongwe sites are clearings in which the surface soil has been much disturbed by diggings and is enriched with malachite particles from underlying ore deposits.

A study of plant colonization of some of the old mine dumps at Chongwe is of interest. The soil contains as much as 1 per cent copper and even after more than 20 yr of exposure few plants have managed to establish themselves on the dumps. Only some clumps of *B. homblei* and the grass *Chloridion cameronii* are found. On analysis it was seen that while *B. homblei* accumulated 160 p.p.m. of copper, *C. cameronii*, in the same conditions, contained little more copper than would be found in plants growing on non-mineralized soils.

The toxic effects of copper are not entirely escaped by *B. homblei*. Even in the early growing season (November) chlorosis is frequently seen in the plant. This increases

Table 1. COPPER CONTENT OF *Becium homblei* FROM DIFFERENT SITES

No. of sample	Baluba	Colossus 1	Site Colossus 2	Allies	Chongwe
1	110 (90)	56 (108)	23 (64)	35 (335)	104 (7,509)
2	95 (110)	60 (100)	20 (52)	40 (410)	128 (585)
3	105 (80)	59 (97)	24 (41)	324 (2,300)	117 (760)
4	—	32 (35)	24 (41)	314 (3,400)	112 (3,160)
5	—	40 (35)	30 (50)	197 (71,500)	96 (5,080)
6	—	20 (46)	17 (64)	159 (63,000)	160 (22,000)

Copper content of plant material expressed as p.p.m. dry weight. Dilute acid soluble copper content of soil at roots of plants is given in brackets.

during the rainy season and by March it was observed at one site that 60 per cent of the plants were at least partly chlorotic.

I have concluded from these results that *B. homblei* will serve as a convenient and very suitable experimental plant for further investigations of copper accumulation and of the effects of the metal on metabolism of plant cells.

I thank the University of Zambia, the Ministry of Agriculture and the Ministry of Natural Resources and Tourism, Government of the Republic of Zambia, and RST Technical Services, and Chartered Exploration, Ltd. (Anglo-American Corporation) for their assistance.

### Phenotypic Restoration of Fertility in a Male-sterile Mutant by Treatment with Gibberellic Acid

THE Tokyo group<sup>1</sup> tested gibberellin on tobacco inflorescences and found them to grow faster and to elongate further; elongation has so far been the most striking plant response to treatment with gibberellins. Floral differentiation, including parthenocarpy, however, has been observed by several workers, among whom are Bonde<sup>2</sup>, Wittwer and Bukovac<sup>3</sup>, Yakar-Olgun<sup>4</sup> and Zatyko<sup>5</sup>. Phatak *et al.*<sup>6</sup> reported that gibberellic acid induced the formation of anthers and the development of pollen in a stamenless tomato mutant. This type of differentiation and development of floral parts is very important in propagating homozygous recessive mutants which involve sterility in one of the sexes in an amphimictic plant species. I describe here my attempts to restore fertility in a spontaneous male-sterile mutant of the barley variety 'Maris Baldric'.

Plants grown in a glasshouse were treated with a single spray of gibberellic acid (GA<sub>3</sub>) at concentrations of 0 (control), 10 p.p.m., 100 p.p.m. or 300 p.p.m. It was applied to leaves of two male-sterile plants when the tip of the bottom awns reached the top of the spike. All ears were bagged just before anthesis. One floret from each of the plants treated at 100 p.p.m. and also one floret from each of the plants treated at 300 p.p.m. had grains formed as a result of the treatment.

Four grains, two from the 100 p.p.m. treatment and two from the 300 p.p.m. treatment, were sown in pots in a glasshouse. One of the grains from the 100 p.p.m. treatment failed to germinate, the other gave a plant which was entirely male-sterile. The two grains from plants treated at the 300 p.p.m. rate germinated and both produced progeny which set from 0 to 12 grains per ear, parts of which were male-sterile.

When the experiment was repeated (results in Table 1) the higher rate showed signs of developing seeds in about 8 days while the lower rate showed these signs in about 14 days. Both the early and the late tillers remained male-sterile.

Spikelets, with restored male-fertility, had anthers which were larger than the normal male-steriles. These enlarged anthers contained pollen with a limited amount of viability—detected by staining with benzedine (J. N. R. Kasembe, unpublished results). Self-fertilization, following the viable pollen formation, resulted in the production of seed which gave homozygous male-sterile plants. These were checked by progeny testing.

Table 1. FERTILITY RESTORATIONS IN SPIKELETS OF MALE STERILE BARLEY FROM 'MARIS BALDRIC' BY A SINGLE SPRAY WITH GIBBERELIC ACID

Concentration	Trial	Total No. of ears	Ears with grains	Total No. of grains
0 p.p.m.	1	16	0	0
100 p.p.m.	1	11	2	10
	2	9	3	21
300 p.p.m.	1	8	5	15
	2	11	8	37

This observation may be important in the production of hybrid barley either as an aid in cereal breeding or in the synthesis of commercial hybrids.

This investigation was carried out under the supervision of Mr R. N. H. Whitehouse, whom I thank for his encouragement and helpful criticism. I also thank the director of the institute, Dr G. D. H. Bell, for his interest in the problem, the Tanzania Government for giving me an extended leave of absence from the Ministry of Agriculture, and the Association of Commonwealth Universities for sponsoring my studies at Cambridge.

## PSYCHOLOGY

### Genetic Relationships, Choice Models, and Sucrose Preference Behaviour in Mice

BEHAVIOURAL geneticists have criticized mathematical models of learning and choice which do not consider genetic and other individual difference parameters<sup>1,2</sup>. No one, however, has demonstrated empirically that genetically related variables aid in determining how well a given model will fit the data. I have found it necessary to include familial parameters within the framework of probabilistic models.

Luce<sup>3</sup> developed a simple and powerfully flexible model of individual choice behaviour, when he derived equations which utilize data from one experiment to predict the choice of the same subject in an entirely different experiment. Equation (1), adapted from Luce's model, was used in this sucrose preference study for such predictions

$$\hat{P}(i|i,k) = \frac{1}{1 + \left( \frac{P(K|i,j,k)}{P(i|i,j,k)} \right)} \quad (1)$$

where  $\hat{P}(i|i,k)$  is the estimate of the probability of selecting solution  $i$ , when the animal is given a simultaneous choice of concentrations  $i$  and  $k$  (two bottle experiment).  $P(i|i,j,k)$  is the probability of selecting solution  $i$ , when the same subject is given a simultaneous choice of concentrations  $i$ ,  $j$  and  $k$  (three bottle experiment). This equation is an application of Luce's results concerning the independence of irrelevant alternatives and his constant ratio rule. It is relatively common in studies of preferences for liquids to use the proportion of total liquid intake from a solution as an index of preference. To interpret Luce's model in this context, the proportion of liquid intake from a solution will be taken as an operational definition of probability.

The same animals were used in both investigations. In the prediction experiment thirty-seven subjects were taken from a four way cross population ( $AR \times CD$ ) derived from  $A/Crg1$ ,  $R/III/Crg1$ ,  $C57BL/Crg1$  and  $DBA/Crg1$  strains of mice. These animals fell into four full-sib families, with more than one litter in each family, and ranged in age from 99 to 174 days at the start of the experiment.

Each subject was placed in a single cage and simultaneously presented with a choice of 30 per cent, 45 per cent and 60 per cent (w/v) concentrations of sucrose. The

Table 1. COMPARISON OF THE MEAN PREDICTED AND OBSERVED VALUES OF  $P(i|j,k)$ 

	Mean	Standard deviation
Observed value	0.648	0.164
Predicted value	0.620	0.157

$i$  is 30 per cent and  $k$  is 60 per cent sucrose solution. Predictions were generated by employing the data from the first experiment. Standard deviations are also included.

subjects drank these solutions from 25 ml. graduated cylinders fitted with non-reactive stoppers and stainless steel drinking tips. The three concentrations remained in each cage for 9 days; the position of the cylinders was changed after each 3 days. Total daily fluid intake from each solution was recorded to the nearest 0.1 ml. In addition, laboratory chow was available at all times during the experiment.

After about 2 weeks, Luce's model was tested in a different way. In this experiment the same subjects were given a choice between 30 per cent and 60 per cent sucrose for 2 days. Again liquid consumption was measured to the nearest 0.1 ml., and food was available at all times.

The scores for raw intake were converted to proportions of total intake from each solution. In the first experiment preferences change only slightly from day 4 to day 9, and so I decided to use these measures in testing the model. The data from the 2 day exposures to 30 per cent and 60 per cent solutions were also combined for this analysis.

If  $i$  is 30 per cent,  $j$  is 45 per cent and  $k$  is 60 per cent sucrose, then by applying equation (1) each subject's preference in the first study was used to predict its preference in the second experiment. Thirty-seven predictions were made in this way. Table 1 compares the mean and standard deviation of the predictions with the observed mean and standard deviation. At this level of analysis Luce's model fits the data relatively well, but the plot of each subject's prediction on one axis and the observed preference on the other axis shows a large amount of scatter (Fig. 1). If the model accurately predicted each individual's sucrose preference, all points on the graph would tightly cluster around the line  $y=x$ , but this is not so. The correlation,  $r$ , between predictions and observations, is 0.590, and  $r^2$ , the proportion of variability observed in the second experiment which the model accounts for, is 0.35. Thus the predictions only determine 35 per cent of the observed variability in preferences.

Fig. 1. A scatter diagram showing the relationship between predicted and observed preferences as a function of families. The reference line  $y=x$  has been drawn to demonstrate theoretically perfect predictions, and it does not represent the actual regression line. (●) Sibship No. 1; (+) sibship No. 2; (—) sibship No. 3; (△) sibship No. 4.

Fig. 1 also shows how well each of the four groups fits the model. The first sibship lies in the vicinity of the line  $y=x$ , and therefore the model accurately describes the preference behaviour of this group. With one exception the subjects in sibships 2 and 4 lie above this line, while all the individuals in sibship 3 fall below it. The scatter of points around the line of perfect prediction seems to be intimately connected to membership in family groupings. Thus if one or more of those particular sibships were not included in this study, the close correspondence between the predicted mean and observed mean might not have occurred.

To check the relative importance of this genetically related variable, a deviation score was calculated for each subject. A deviation score is defined as the difference between the observed and predicted proportions,  $P(i|j,k) - \hat{P}(i|j,k)$ , where  $i$  = 30 per cent and  $k$  = 60 per cent sucrose. These scores vary in both magnitude and sign. The data were next linearly transformed to positive numbers and subjected to an analysis of variance ( $F=16.051$ ,  $P<0.001$ , degrees of freedom=3,33). The proportion of total variance determined by sib-relationships, as estimated by the intra-class correlation,  $R$ , equals 0.61. The confidence interval for  $R$ , which can be used as an index of sampling variability, is  $0.21 < R < 0.88 = 0.98$ . Thus it is 98 per cent certain that the true value of  $R$  falls within this interval.

In order to estimate the reliability of these findings in another way, between the first and second experiments the same subjects were given a simultaneous choice of 0 per cent (tap water), 30 per cent and 60 per cent sucrose. The procedures were the same as those used in the first experiment cited. Calculations of  $\hat{P}(i|j,k)$  and deviation scores were again made for all thirty-seven subjects. The correlation between the deviation scores found from both experiments was 0.715, which suggests that these systematic individual differences in predictive accuracy are reliable and consistent differences.

The model was originally intended to describe the choice behaviour of individual subjects. These results show that (a) the close correspondence between the predicted and observed means may be a spurious finding (consider Fig. 1 without including sibship No. 3); (b) the actual correlation between the predictions and observed values accounted for only 35 per cent of the variability in preferences; and (c) sibship groupings determine approximately 61 per cent of the variability in predicted accuracy. Thus because the magnitude and sign of these deviations from perfect predictions can be greatly affected by the sibships used, it seems reasonable to include a genetically related parameter in future models of choice and preference.

## ANIMAL BEHAVIOUR

### Stimuli provided by Courtship of Male *Drosophila melanogaster*

DURING courtship *Drosophila melanogaster* males perform a movement termed vibration<sup>1</sup>, in which one wing is held out horizontally at right angles to the body and vibrated in the vertical plane. This movement is very important in stimulating sexual receptivity in the female<sup>2</sup> and the

stimuli produced by vibration are perceived through the females' antennae<sup>3</sup>. The exact nature of the stimulation is unknown, although there is evidence that it is not olfactory<sup>4</sup> as was previously thought, nor is it visual, for success of mating is not significantly reduced in the dark<sup>5</sup>. Sound is produced during vibration, and so it is possible that the stimulus is auditory<sup>6</sup>. The sounds consist of pulses of between 180 and 350 cycles/sec with a pulse repetition rate of 29/sec at 25° C. Each sound pulse is possibly produced by one up and down movement of the wing as the sound record shows a single damped oscillation (Fig. 1).

In order to demonstrate experimentally the characteristics of the stimulation we attempted to provide an analogue for vibration and to see whether it was possible to use this to supplement the courtship of males with their wings removed. Such males have been shown to be very unsuccessful in obtaining mates although their courtship remains persistent and they attempt to copulate just as frequently as normal males<sup>2</sup>.

Virgin wild type flies were collected from stock bottles and kept in vials, ten flies in each vial, with standard *Drosophila* medium. Wingless males were obtained by lightly etherizing the flies and amputating the wings with a scalpel as near the body as possible. It is possible by this method to remove between 80 per cent and 90 per cent of the wings. The operations were carried out on the day after ecdysis and all experiments were done when the flies were 3 days old, for females are known to be maximally sexually receptive at this age<sup>7</sup>. A mating chamber 27 mm in diameter and 10 mm deep was used, the roof and floor being of fine nylon mesh and the wall of aluminium. A small aperture in the wall allowed flies to be introduced into the chamber. An electronic circuit was built the electrical output of which faithfully simulated the electrical record of the sounds recorded during vibration. The mating chamber was suspended above a loudspeaker through which the simulated vibration sounds could be reproduced. The initial experiments showed that while the sounds did facilitate the mating of wingless males the number of copulations did not approach the level achieved by the normal winged controls. It seemed possible that net movement of air could occur as a result of vibration. In order to simulate this an extractor fan was arranged to produce a current of air through the cell. The pulse repetition rate of the sounds produced during vibration is temperature dependent, and so all the experiments were carried out at  $25 \pm 1^\circ$  C. The experimental arrangement is illustrated in Fig. 2.

It is difficult either to measure or calculate actual values of sound intensity and velocity of air movement which are produced by the normal vibration of males. The levels were therefore rather arbitrarily set in such a way that the artificial stimuli did not produce any gross changes in the behaviour of the flies other than changes in mating speed. Even slow air movements, however, seemed to reduce ambulatory activity although the flies appeared to habituate to this stimulus in a few minutes.

Ten males and ten females at a time were introduced into the mating chamber and the number of copulations

Fig. 1. Oscilloscope records of the sound produced by vibration at slow and fast speeds to show the regularity of the pulse repetition rate and the shape of the sound pulses respectively. Time marker, 50 cycles/sec.

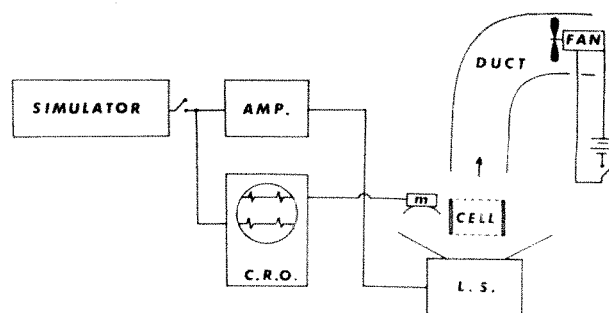

Fig. 2. Experimental set-up for providing simulated courtship vibration. m, Microphone for monitoring audio output from the loudspeaker (L.S.). For further explanation see text.

during the first 15 min was scored. Once copulation had commenced males were not observed to dismount within the test period. Males did not therefore mate more than once. The following experimental groups and controls were tested as follows: normal winged males without sound or air current; wingless males without sound or air current; wingless males with sound but without air current; wingless males without sound but with air current; and wingless males with both sound and air current.

The number of copulations within groups in a series of replicate experiments was not normally distributed in all the groups. This was principally because of the large number of nil copulations scored particularly for wingless males without sound or air current. Also the variances were not independent of the means. For these reasons Wilcoxon's method, which is distribution free, was employed to test for differences between the groups<sup>8</sup>. The percentage copulations in each group are given in Table 1 and the results of the statistical analyses in Table 2.

Table 1. PERCENTAGE COPULATIONS ACHIEVED BY NORMAL WINGED MALES AND WINGLESS MALES SUPPLEMENTED BY ARTIFICIAL STIMULI

Wings	Air current	Sound	No. of experiments	Percentage copulations
+	-	-	14	35.0
-	+	+	14	42.9
-	-	+	14	25.0
-	+	-	14	15.0
-	-	-	13	3.1

Table 2. STATISTICAL COMPARISONS BETWEEN COPULATIONS ACHIEVED BY WINGLESS MALES WITH DIFFERENT ARTIFICIAL STIMULI

	- Wings + Sound - Air	- Wings - Sound + Air	- Wings - Sound + Air
- Wings - Sound - Air	$P < 0.02$	$P < 0.001$	$P < 0.0001$
- Wings + Sound - Air		$P < 0.12$ Not significant	$P < 0.001$
- Wings - Sound + Air			$P < 0.001$

Either the sound or the air current is on its own sufficient to facilitate the mating success of wingless males while the two stimuli provided concurrently have an even more conspicuous effect. It seems from the results that the simulated stimulation is as effective as or even slightly more effective than the natural vibration. It is not justified, however, to make a direct comparison between the number of copulations achieved by winged and wingless males in the mating chamber which we used for these experiments. The wings are used not only to provide sexual stimulation, for competing males flick their wings at one another. This movement has an inhibiting effect on the courtship of males and possibly also has a similar effect on females. In the limited space provided by the mating chamber there is a considerable amount of interaction between winged males, and this is markedly less apparent in experiments with wingless flies. For this reason the results obtained with winged flies have not been treated statistically but are included to give an approximate indication of the natural situation.

The results suggest that the simulated stimulation provided by our apparatus is analogous to that of normal vibration. There therefore seem to be two components of the stimulation, one phasic and one tonic. It is not possible to decide from these results whether the females become receptive because of the heterogeneous summation of the two components or whether the tonic one, that is, net air movement, acts by inhibiting walking in the females, thus making them more accessible to copulatory attempts by males.

It has been shown electrophysiologically in several insects, including *Calliphora*, whose antennae are similar in structure to that of *Drosophila*, that the antennae respond separately to both tonic and phasic stimuli<sup>9</sup>. It is likely therefore that the antennae of *Drosophila* will have similar characteristics. We have observed that the aristae of the antennae resonate in response to a pure tone of between 180 and 220 c.p.s. which is within the range of frequency found during vibration and is also the same as the wing beat frequency during flight<sup>10</sup>. The correspondence between antennal resonance and the wing beat frequency has also been noted in *Anopheles* species where the flight sounds of the females serve to attract males<sup>9</sup>. The arista of *Drosophila* does not appear to resonate in response to either the stimulated or the normal vibration sounds, however, presumably because the energy level is much lower. Further evidence for the involvement of the arista is provided by Manning, who has demonstrated that if the aristae of a female are immobilized she becomes sexually unreceptive (personal communication). It is possible that the intermittent signal of vibration has evolved so that the female can discriminate between the stimuli provided by courtship and flight.

The vibration of different species of *Drosophila* is known to differ with respect to both pulse repetition rate and to intra pulse frequency<sup>11</sup>. These changes could be evolved as an aid to sexual isolation. Our simulator is variable for both these characteristics and this will allow us to analyse whether these signals are indeed species specific in their effects.

We thank Dr B. C. Clarke for his advice and Dr A. Manning for criticizing the manuscript.

### Divergent Thinking and Science Specialists

EMPIRICAL studies casting doubt on the IQ as an adequate summary of an individual's intellectual capacities<sup>1,2</sup> have lent support to the increasing use of tests of "divergent thinking", and to attempts to show that such tests are usefully related to academic achievement, especially in science<sup>3,4</sup>. These tests are distinguished from more conventional tests of intellectual capacity by the fact that they are designed to measure originality and flexibility. The older tests, by contrast, give greater emphasis to the finding of strictly logical, "correct" solutions. Two chief points about the newer tests can be emphasized: the first concerns their doubtful long-range validity, because it

has not been shown that they correlate with later achievement in the way that ordinary IQ tests do<sup>5</sup>, and the second centres on Hudson's report<sup>6</sup> that sixth form science specialists in British schools are usually convergent in their intellectual bias.

Some data collected at the University of New England are relevant to these two issues. In 1963, out of a total of 336 first year students, the 100 men with the highest marks in the New South Wales matriculation examination were selected. During their first two days in the university this group of men completed five convergent tests (vocabulary, verbal reasoning, verbal comprehension, logical reasoning, and reading speed), and six divergent tests (product improvement, unusual uses, ask and guess, picture construction, figure completion, and parallel lines)<sup>7,8</sup>. The convergent tests were scored in the usual way by tallying correct responses, while divergent tests were scored on the dimensions of fluency, flexibility, and originality in the case of the verbal tests, and fluency, flexibility and elaboration in the case of the non-verbal. Later a single score was obtained for each divergent test by simply summing the three sub-scores for that particular test. After the scores for each individual test had been standardized to avoid difficulties associated with large differences in means and standard deviations, total scores for divergence and convergence were obtained for each man by summing his scores on the divergent and convergent tests. Finally, total scores on divergence and convergence were again standardized and an "intellectual bias" score was obtained for each man by subtracting the convergence score from the divergence score. Positive scores thus indicated a preference for divergent intellectual functioning, negative scores a preference for convergent. No account was taken of level of scores, but, because all the men were very able, level was regarded as relatively unimportant.

Included among these 100 very able entrants to the university were thirty-eight of the sixty-three men who entered science departments in 1963. The performances of these science undergraduates during the 4 yr period, 1963-66, provided the data with which this communication is concerned. Two issues involving these students can be examined. To what extent are they predominantly convergent in their intellectual bias? To what extent are individual differences in bias, as against level, related to undergraduate achievement?

Twenty members of the group displayed the convergent bias and eighteen the divergent. These proportions can be compared with those prevailing in the total group of 100 able men, fifty-five of whom had convergent biases and forty-five divergent. On the basis of the distribution of divergence and convergence in the full group, twenty-one men would be expected to show the convergent bias in any chance sub-group of thirty-eight. Thus the group of able science students did not contain an unusual number of convergent thinkers when compared with all very able men entering the university.

Convergers and divergers did not differ so far as matriculation marks were concerned. The mean matriculation mark of the twenty convergers was 424.7 (standard deviation, 54.9) and the corresponding mark for the eighteen divergers was 411.7 (standard deviation, 41.6). A further comparison of examination performances was made at the end of first year. Each man had been examined in four subjects and allotted a result ranging from FF, indicating a clear-cut fail, to HD, indicating very superior performance. The range of results was converted to a six-point numerical scale ranging from 0 for FF to 5 for HD, and a total achievement score out of a possible 20 calculated for each man. Again, there was no significant difference in achievement between the convergers (mean, 9.30; standard deviation, 4.04) and the divergers (mean, 9.28; standard deviation, 3.97).

When, however, the question of whether or not students proceeded to honours was considered, the position was

quite different. In Australian universities, students enter as candidates for the ordinary degree and are admitted to honours courses on the basis of superior performance in the first 3 yr. Honours requires an additional year. Of the total male science entry for 1963, nineteen completed 4 yr honours degrees in 1966. Fifteen of these nineteen were included in the thirty-eight men with whom this communication is concerned, scarcely surprising in view of the fact that the thirty-eight men were selected on the basis of superior matriculation performance. No fewer than eleven of these fifteen were divergers, only four were convergers. Thus although academic performance at matriculation and first year levels had not differed, markedly dissimilar numbers of the two groups had gone on to honours. The proportions differ significantly from those which would be obtained if there were a chance relationship between convergence/divergence and the taking of honours ( $\chi^2$ , 5.09; degrees of freedom, 1;  $P < 0.025$ ).

The distribution of honours students by departments is also interesting. Convergers receiving honours were confined to mathematics (two), physical chemistry and physics. On the other hand, divergers received honours in mathematics (five), physical chemistry, biochemistry, physics, geology, biology and zoology. Of the total of

## GENERAL

### Microbarograph Record of Waves from the Chinese Thermonuclear Explosion on June 17, 1967

AN unusual train of waves, characteristic of a distant and violent disturbance of the atmosphere, began to be received on a microbarograph<sup>1</sup> in Aberdeen at about 0545 h G.M.T. on June 17, 1967. The unusual train, which lasted about an hour, was superimposed on a much longer and more usual series of waves of period about 12 min and amplitude 250 microbars; such waves, which are of natural origin, are characteristically received during meteorological inversions.

Fig. 1. Microbarograph record of waves from the first Chinese thermonuclear explosion taken at Aberdeen 0500–0700 h G.M.T., June 17, 1967. Full scale deflexion is roughly 270 microbars for waves with a period of 2–4 min.

nineteen honours degrees awarded in 1966, eight were with first-class honours. Seven out of these eight went to the sub-group of thirty-eight, so that only one man who was not in the highest scorers at matriculation level obtained first-class honours in science 4 yr later. Five of the seven firsts went to divergers. In the case of mathematics, three out of four firsts went to divergers.

Although these results are clearly of limited general application because of the small number of students involved, they are interesting in that they do not agree with findings for British sixth form schoolboys<sup>6</sup>. Furthermore, they also suggest that later years of undergraduate study, and especially the honours year, may give students more opportunities to utilize divergent thinking skills, although it is doubtful if any undergraduate course affords many such opportunities.

I thank the Student Research Unit of the University of New England for making available to me data collected by them in 1963.

<sup>1</sup> Hudson, L., *Contrary Imaginations* (Methuen, London, 1966).

<sup>2</sup> Gibson, J., and Light, P., *Nature*, **213**, 4415 (1967).

The unusual train is likely to have arisen from the first Chinese thermonuclear explosion, announced some hours later. Two small disturbances on a vertical seismograph were also recorded at Aberdeen at 0050 and 0147 h G.M.T. on the same day. If the earlier of these disturbances originated from the explosion, the range was about 4,000 miles, which is consistent with an origin in Western China. The peak-to-peak amplitude at Aberdeen (where I am indebted for the calibration and maintenance of the microbarograph to Mr T. P. Gill) of the largest atmospheric waves from the bomb was about 270 microbars. This may be compared with amplitudes at Aberdeen of 350 microbars and 1,000 microbars for the Russian explosions of 25 and 50+ megatons TNT equivalent over Novaya Zemlya on October 23 and October 30, 1961. Because the Chinese explosion was at roughly twice the range of Novaya Zemlya it thus appears to have been equivalent to that of between 20 and 30 megatons TNT. This figure is consistent with the 1.5 min period of the largest waves in the train<sup>2</sup>.

## BOOK REVIEWS

## HERITAGE OF MENDEL

## The Origin of Genetics

A Mendel Source Book. Edited by Curt Stern and Eva R. Sherwood. Pp. xvi + 179. (London: W. H. Freeman Company, Ltd., 1966.) 36s. cloth; 18s. paper.

## Heritage from Mendel

Edited by R. Alexander Brink with the assistance of E. Derek Styles. (Proceedings of the Mendel Centennial Symposium sponsored by the Genetics Society of America, 1965.) Twenty-seven contributors. Pp. xii + 455. (Madison, Milwaukee, and London: The University of Wisconsin Press, 1967.) 75s. net; \$10.00 clothbound; \$7.5 paperbound.

If we look for the sources of genetics we are bound to look first at Mendel's paper on peas. Eva Sherwood has made a new English translation of this paper and to it she has added a series of other translated and reprinted articles. First there is Mendel's seven-year correspondence with Carl Nägeli, that eminent but opinionated botanist. Secondly, there is Mendel's fruitless paper on the breeding of what we now know to be sub-sexual *Hieracium*. Thirdly, there are the articles and letters of the rediscoverers, both the enquiring and ingenuous Correns and the dogmatic and disingenuous de Vries. And to cap the story there is Fisher's startling re-examination of Mendel's numbers.

What of the new translation? The words used in the first English version of Mendel's paper from "character" to "round and wrinkled" have over a period of sixty-six years passed into the language of genetics. An important step in genetics was taken when Bateson showed that the heterozygote in respect of the character difference round-versus-wrinkled could be recognized and the source of the difference explained. The new translator now speaks not of "characters" but of "traits" and not of "wrinkled" but of "angular". No one probably will follow her unfortunate example. So also with other amendments—whatever they may be, for the translator has given us no help in finding them. Her successes and her failures together are therefore likely to pass unnoticed.

The book as a whole, however, we must treat on a different level. It takes us a step forward in understanding Mendel's work. Fisher has said of this work (on page 171 of the present book) what is true of many smaller revelations, that "each generation perhaps found in Mendel's paper only what it expected to find". The first generation indeed found a jumble of words and numbers concerning hybrids and peas. The second generation found genetics. A later generation (in the coming century) will find that Mendel's ideas in this paper reached out so far as to be almost indispensable for a serious and civilized education.

After Fisher's analysis of Mendel's numbers showing that they agreed too well with Mendelian expectations there follows a neat and just re-assessment by Sewall Wright. Neither is concerned, as Mendel was, with the foundations of biology. On the contrary both offer us an exercise in statistical virtuosity. But what a happy exercise it is! Happy also am I to see so much indignation avoided by a posthumous correction now posthumously corrected.

The fact is that if Mendel had taken and discussed all the statistical precautions which his successors have envisaged he might, even in 1900, have missed having any listeners, let alone readers or successors. And, as we may see here, de Vries was incapable of learning from the sim-

plest practices of Mendel how to set out his own numerical records with veracity: he thought a percentage was a good enough statement of his observations. From de Vries back to Mendel and on to Sewall Wright we are taken in one quick journey through a large part of the evolution of statistical understanding.

In *Heritage from Mendel* twenty-one articles, twelve American, nine foreign, discuss genetics as it seems to their authors today. Nearly all are concerned with looking very closely and deeply at problems covering separately, and with little overlap, a large part of genetics. Of the connexions between these articles the authors and their readers may or may not be aware: we cannot tell.

This book makes clear, if it was not clear already, that the heritage of Mendel has now attached itself to the whole movement of biology. It is not therefore possible to produce a volume with the purpose expressed by the present editors of honouring Mendel without some attempt at co-ordination and elucidation before and after the manuscripts are collected. Of such an attempt this *dysposium* provides evidence in a few articles which indicate the development of their subject. In this way Beermann, Sewall Wright and Crow tell us things which connect one another. And one contributor, Beadle, tells us things which even connect with the origin of genetics. These writers indicate the size of the opportunity that has been missed.

## DEVELOPMENT OF PSYCHIATRY

## Mental Illness

Progress and Prospects. By Robert H. Felix. Pp. 110. (New York and London: Columbia University Press, 1967.) 35s. 6d. net.

THIS book consists of four lectures given by Professor Robert H. Felix, Dean of the Medical School of St. Louis University, at Columbia University. The first lecture describes the history of mental illness from the earliest times until the nineteenth century. The second lecture deals with the realization in America, during the Second World War, that there were thousands of people who were mentally unfit, ranging from the insane to the neurotic. Between 1942 and 1945 out of approximately 15 million examinations for admission to the American armed forces 1,875,000 individuals were found to be suffering from neuropsychiatric disability. Out of every 100 men examined twelve were rejected for this reason. They exceeded the numbers assigned to the Pacific theatre of operations during the war. This was not all. It was found that those in mental hospitals were increasing, as for example, from 183.6 in each 100,000 in 1904 to 412.6 in each 100,000 in 1950.

The third lecture concerns the advances made in dealing with the 47 per cent of the mentally ill patients, out of the 750,000 sick in hospital, on any one day in America. Professor Felix points out that the discovery of tranquillizers which have had such a beneficial effect in reducing the number of patients in mental hospitals was really incidental. Chlorpromazine, for example, was discovered when research was being carried out on hypothermia in France, and reserpine was found during work on *Rauwolfia serpentina* as a hypotensive element.

The last lecture seems to be the most unsatisfactory of the four, although it might have been expected to be the most exciting. The author seems to have become bogged down with administrative matters, instead of scientific possibilities. He does not mention that there are tremendous advances to be made in the causes of mental deficiency, the reduction of organic dementia caused by unsuspected agents, the elimination of psychosis by the discovery and removal of the causes of schizophrenia and manic depression. The tranquillizers, for example, have reduced the resident population of the mental hospitals

of the United States from 558,922 in 1955 to less than 490,754 in 1964 and this in spite of the admission of 302,946, the largest number in history, in 1964. This surely is only the beginning. If research is widened the vaunted mental services will be unnecessary.

In spite of this criticism those interested in American psychiatry, particularly from the administrative point of view, will find this book interesting. It is unfortunately expensive for its size, although well produced.

CLIFFORD ALLEN

## SPACE IN THE BRAIN

### Brain Tissue Electrolytes

By A. Van Harreveld. (Molecular Biology and Medicine Series.) Pp. xii + 171. (London: Butterworth and Co. (Publishers), Ltd., 1966.) 44s.

THE subject matter of this short (171 pages) and rather expensive book is more restricted than the title implies. The author deals with the problem of the size of the extracellular space in the central nervous system, which is usually assumed on the basis of conventional space techniques and electron microscopy to be a mere few per cent of the tissue volume. Van Harreveld assembles convincing evidence that this traditional view is probably incorrect and that the size of the space is not very different from the size in other parts of the body.

The large amounts of extracellular ions, sodium and chloride, found in nervous tissue, the low electrical impedance of the cerebral cortex and the loose packing of neural elements in electron micrographs of tissue frozen within half a minute of circulatory arrest support his contention that the space is about 20 per cent of tissue volume. Earlier measurements of the extracellular space from electron micrographs had not allowed for the very rapid diminution in size of the space that takes place during fixation of the tissue by perfusion. He describes how asphyxia and spreading depression result in a rapid increase in tissue impedance which he attributes to the movement of extracellular ions and water into the depressed cells with consequent reduction in the low impedance extracellular component of the tissue.

Within its compass this is a well written and well argued book on the subject in which the author has done notable experimental work. I warmly recommend it.

J. T. FITZSIMONS

## OUR FAVOURITE REMEDY

### The Salicylates

A Critical Bibliographic Review. Edited by M. J. H. Smith and Paul K. Smith. Pp. xiv + 313. (New York and London: Interscience Publishers, a Division of John Wiley and Sons, 1966.) 80s.

THIS is an exemplary publication—a model of what a monograph can be. It is, above all, about an interesting subject—a family of drugs dating back to the earliest herbal remedies using leaves, bark and fruits of plants containing methyl salicylate ("oil of wintergreen") and glycosides of 2-hydroxybenzyl alcohol (such as salicin), which have withstood all attempts by the pharmaceutical industry to render them obsolete. Aspirin (acetyl salicylic acid), introduced in the 1890s, is still the dominant drug today, not only in tonnage consumed but as first choice whenever an antipyretic, analgesic, mild sedative or anti-rheumatic agent is required. It is also remarkably safe, a property which many less effective drugs conspicuously lack, allowing us easy access to it. To the pharmacologist and physician alike, the question "How does it work?" is

still a challenge. If some answers are found to that question before another 100,000 tons of aspirin are consumed, it will be largely as a result of the work summarized in this monograph.

The book is therefore timely. It is also well written, well documented, well produced, reasonably priced and should be of considerable interest to a wide range of readers. It is a fine tribute to the late Paul K. Smith, whose inspiration is apparent in this volume but who unfortunately died before the manuscript was prepared.

The subtitle and preface indicate that this is not an exhaustive survey of the literature. The aims of this volume, which are to update an earlier monograph of the same title (published in 1948) and to critically evaluate various hypotheses which have been advanced to explain the multiple actions of the salicylates, are certainly achieved. The introduction gives a complete synopsis of the book and is a model of what an "instant survey" should be. Four of the six chapters are written by M. J. H. Smith, who modestly designates himself on the dust jacket merely as a co-editor. There is a brief subject index. Every chapter is a review in itself and, appropriately, each contains a summary—a welcome feature deserving wider emulation.

Considerable attention is given to biochemistry and it is no accident that so much more is known about the salicylates than, for example, colchicine or caffeine, because problems such as the disposition of the salicylates *in vivo* and their effects on enzyme systems have been investigated by essentially biochemical techniques. These particular aspects of a drug's pharmacology are not readily discerned by some of the biophysical techniques and electronic hardware which the average pharmacologist tends to use as his stock in trade.

The description of the absorption and metabolism of salicylate in the first chapter should be required reading for all who hope to investigate the pharmacokinetics of other drugs. Due emphasis is given to the ways in which the pharmaceutical formulation can profoundly influence the rate of gastro-intestinal absorption. There are clear explanations of two paradoxes: the increase in drug half-life *in vivo* with increasing drug dosage, and the fact that bicarbonate can both facilitate and antagonize gastric absorption of aspirin. The second chapter emphasizes the multiple sites of action of the salicylates and indicates how an overall metabolic effect can result from a mixture of superimposed effects of these drugs on several different enzyme systems. The nature and consequences of drug action on the multi-enzyme system of mitochondrial energy conservation ("oxidative phosphorylation"), the aminotransferase enzymes and the nucleotide-linked dehydrogenases, are clearly summarized. Much of the third chapter is taken up with disposing of the old heresy that the antirheumatic properties of the salicylates are mediated only through the adrenal cortex, although toxic (as opposed to therapeutic) doses of these drugs are recognized as stimulators of the pituitary-adrenal axis. The action of the drug on thyroid function is also covered in some detail. The fourth chapter discusses the physiology of pain perception and the problems of measuring pain objectively and assessing the potency of non-narcotic analgesics. Evidence is given that unhydrolysed aspirin may be a more effective analgesic than the salicylate anion and that both these forms are effective only when the pain-evoking stimulus is chemical in nature. The chapter on anti-inflammatory activity opens with a pithy and entertaining survey of that nebulous subject, inflammation. This is followed by a sceptical enquiry into the effectiveness of salicylates in influencing experimental inflammatory states in animals and clinical inflammatory disease. Possible sites of drug action in suppressing inflammation are thoughtfully analysed.

The final chapter, on toxicology, considers the association of gastro-intestinal bleeding with salicylate medication as well as the overt toxicology of these drugs. The

multiple action of toxic amounts of salicylates in deranging the plasma anion-cation balance is detailed. The book ends with a very useful description of the various methods of eliminating excess salicylate from the body and discusses the choice of a suitable procedure for treating a given case of salicylate intoxication.

One of the most impressive features of this book is that the argument is never swamped by a sea of facts, although these are plentifully provided, and the clarity of organization is apparent even on cursory inspection. Ill-warranted assumptions are clearly exposed as impediments to more satisfactory explanations of the duration and mechanism of action of the salicylate drugs *in vivo*. One noticeable omission from this otherwise excellent account of these drugs is any specific discussion of their antipyretic properties.

If there is a serious shortcoming in this book, it is the scant attention paid to the physico-chemical properties of both the postulated drug receptors and the various dosage forms of the salicylates (and their metabolites), which ultimately must determine largely the therapeutic or toxic action of these drugs at the molecular level. Salicylic acid is a remarkable chemical—a relatively strong acid ( $pK_a$  3.0) which, unlike many such acids, can pass from an aqueous phase into or across a lipid phase at physiological  $pH$ . This is possible because the intramolecular hydrogen bond between the ionized carboxyl group and the undissociated phenolic group effectively diminishes the molecular hydration of the drug anion. Some recent studies, reported in *Biochemical Pharmacology*, suggest that the salicylate anion can effectively bind to, and thereby neutralize in more senses than one, essential cationic groups of intracellular enzymes and other key proteins. The physical properties of the drug species *in vivo*, therefore, effectively determine both the translocation of the drug (anion) from the extracellular compartment to these active sites within a cell and the subsequent drug binding at these sites, and thus the overall action of the drug.

This book is warmly recommended to all who are concerned with drugs; all pharmacologists can learn something from it. Future authors of pharmacological treatises would do well to follow Professor M. J. H. Smith's example in combining enthusiasm for their chosen interest with clear-headed objectivity, a lucid style and searching critique.

M. W. WHITEHOUSE

## MEASURING CARDIAC FUNCTION

### Ballistocardiography in Cardiovascular Research

Physical Aspects of the Circulation in Health and Disease. By Isaac Starr and Abraham Noordergraaf. Pp. vi + 438. (Amsterdam: North-Holland Publishing Company, 1967.) 110s.

BALLISTOCARDIOGRAPHY has been around for some thirty years and a recent bibliography on the subject lists 1,500 papers. The subject has been a confusing one, much worked in but with little practical impact on cardiology. This book on the subject is particularly useful for three reasons: it distills the essence of the large bibliography; it is written by someone who has been in the field since the beginning and has acquired a sense of proportion and perspective; and finally because the day of the ballistocardiogram may be approaching.

As Dr Starr repeatedly points out, the ballistocardiogram has two unique advantages as a method of investigating cardiac function. The first is its utter simplicity as compared with the other elaborate and traumatic techniques. The second advantage is that it measures the functional state of the heart which other investigations do not. More and more it is becoming apparent that the acceleration of the blood leaving the heart is a better index of function than either blood pressure or volume output.

Does this book explain why in spite of these advantages the ballistocardiogram has made so little impact on clinical medicine? It does, but only obliquely, for the senior author is himself so convinced of the value of the ballistocardiogram (and with good grounds) that he is eager to put over this idea.

The tone of the book is a very personal one; whenever there is a point of controversy or doubt the senior author firmly states his own point of view and he states it with well-earned authority. Rather than being a fault this personal view is one of the main advantages of the book. The author knows his field thoroughly and can afford to be sane, sound and sensible about a subject which is often brought into disrepute by the over-enthusiasm of those who start using a tool for the first time. This virtue is especially evident in the section on the reading of records. Here the senior author points out that although better instrumentation may make more refined measurements possible, with the older records all that can be done is to classify them into four groups ranging from the normal to the grossly abnormal, on a pattern basis.

The early part of the book contains a clear mathematical exposition of the physical basis of the ballistocardiogram by Dr Noordergraaf. This is probably above the head of the average cardiologist and might on that account have been relegated to an appendix except that the validity of this method does depend so entirely on sound physics and correct instrumentation. Dr Noordergraaf's mathematical model of the circulation gives surprisingly good imitations of the ballistocardiogram, and so do Dr Starr's well-known cadaver experiments, but no description by mathematics or by models can exclude the possibility of alternative descriptions.

The possibility that movement of the heart wall contributes to the ballistocardiogram is rather summarily dismissed by Dr Starr on the dual grounds that his own cadaver experiments with blood movement alone could mimic the ballistocardiogram pattern and also that the experiments purporting to show the contribution of movement of the heart wall were grossly unphysiological. It should, however, be possible to settle this point in a more elegant manner by injecting carbon dioxide into the left atrium of animals while continuously recording the ballistocardiogram.

Most of the book is devoted to the use of the ballistocardiogram in estimating cardiac function in man—and that is as it should be. Much of the early difficulty was caused by inadequate instrumentation, and it is no doubt justifiable to question the adequacy of the instrumentation used to produce records which do not agree with one's own, but it does reinforce the unfortunate impression that the ballistocardiogram record depends far more on the competence of the technique than on the state of the heart—and this is one of the prime reasons it has been distrusted by outsiders. Quite early in the book the shin-bar method of obtaining records is dismissed as being too full of artefacts, yet in the results section a large proportion of the findings offered are stated to have been obtained in this way.

Perhaps the main criticism of the section on the ballistocardiogram findings in various cardiac states is that the authors have tried to be too comprehensive and too fair to other workers. The result is that the good studies are lost among a plethora of rather indifferent studies of which some are no more than anecdotal. Similarly, those conditions in which the ballistocardiogram has shown itself to have a definite use are rather diluted by the inclusion of every possible condition in which the method has been tried.

One of the main troubles with this method points to a dilemma in medicine itself. With increasing age the number of abnormal ballistocardiogram records obtained increases until in the 50–59 age group it may be as great as 34 per cent. Does this mean that some other factor connected with ageing has distorted the record and thus

limited the use of the method (for the number of abnormal records far exceeds the number of patients with cardiac impairment discernible on any other grounds); or should we maintain faith in the method and create a new disease of "presbycardia" which can only be detected by ultra-sensitive ballistocardiography? The data offered on the long-term follow-up of patients with such abnormal records certainly tend to support the latter view. This may not matter too much at the moment because little can be done to improve such hearts, but this may not always be the case. Furthermore, there are times when it is important to exclude the slightest hint of cardiac disease (for example, in testing air-line pilots). It is not made clear in the book whether the ballistocardiogram would be fair for this purpose.

With regard to the follow-up of abnormal records, several examples are shown together with a note of the unfortunate outcome. It may be felt that such anecdotes do not prove anything because normal records might be followed by such an outcome and many abnormal records are not. I feel, however, that there is an advantage in showing such records in order to acquaint the reader with the order of change that might be expected with the method.

One of the most interesting sections of the book deals with the effects of drugs (for example, digitalis and anaesthetics) on cardiac function and this would seem to be a useful area of study. Perhaps too much of the book is devoted to comparing records between different people and establishing norms as opposed to testing cardiac function by comparing the record in one patient before and during some manoeuvre. Such manoeuvres are technically difficult if they involve the patient leaving the ballistocardiography table and then returning. One simple manoeuvre not mentioned is the administration of a drug by aerosol during continuous recording.

A point well made by Dr Starr is the importance of the ballistocardiogram in assessing therapy, as in the excellent work done by Dr Deuchar with reference to aortic valve disease and cardiac surgery. The best way the ballistocardiogram can demonstrate its usefulness to unbelievers is in certain definite conditions rather than as a diffuse multi-purpose test.

In the final chapter Dr Starr effectively indicates the place of the ballistocardiogram in medicine and leaves no doubt that with robust instrumentation this method must become accepted as routine. For this reason, and also on its own account, this book belongs in every cardiology department.

EDWARD F. DE BONO

## FUNGAL COMMUNITIES

### Ecology of Fungi

By R. K. Robinson. (Modern Biology Series.) Pp. 116. (London: The English Universities Press, Ltd., 1967.) 21s. net.

In these days of increasingly precocious specialization in the education of scientists, it is becoming ever more important for young biologists not to miss the right choice through sheer ignorance of all the possible alternatives. Dr Robinson's book is a good example of what can be done in about a hundred pages of text to introduce a beginner to a new field of biology. The fungi, because of their larger cell size and much greater morphological diversity, provide a better introduction to the science of microbial ecology than do either the bacteria or the actinomycetes, so that identification into species is thereby both more rapid and more certain. In this book, Dr Robinson surveys the subject of fungal ecology in four chapters; an introductory one on fungal morphology, organization and classification is followed by others on saprophytic fungi, root-inhabiting fungi, and parasitic fungi, respectively. The book is illustrated by thirty-

eight text-figures, some of them original; among the latter, Fig. 20B is so unlike its subject (conidia of *Helminthosporium sativum*) as to suggest a mistake in labelling. Dr Robinson's treatment of his subject in these four chapters is comprehensive and very readable, as well as being thoroughly up to date. He is likely to be widely successful in explaining to young biologists what the science of microbial ecology in general, and of fungal ecology in particular, is about.

S. D. GARRETT

## ADVANCED LIMNOLOGY

### A Treatise on Limnology

By G. Evelyn Hutchinson. Vol. 2: Introduction to Lake Biology and the Limnoplankton. Pp. xi + 1,115. (London and New York: John Wiley and Sons, Inc., 1967.) 310s.

It is just ten years since the appearance of the first volume of this treatise, treating the geography, physics and chemistry of lake systems which to many limnologists has been a model of concise scientific writing and a mine of information. This second volume continues the fine tradition although some may be disappointed that it does not complete the treatise, but the subject has expanded such that productivity of the plankton, non-planktonic communities, typological, stratigraphic and developmental aspects are left to a third volume. There is no doubt that this was the only solution if the comprehensive coverage of the first volume was to continue through the biological part of the treatise. Let me say at once that this is a most impressive volume, combining as usual in Hutchinson's work an extensive review of the literature with a masterly synthesis of ideas and an original approach to so many aspects. Before the preface is an extract from Hudson and Gosse's classic work on the Rotifera—it is a lyrical passage and typifies Hutchinson's obvious fascination with the natural history of freshwater life. But this book is a natural history carried through to the most rigorous scientific analysis culminating in mathematical models wherever possible.

The opening chapter on the nature and origin of the freshwater biota starts with a synopsis of classification of the plant and animal groups represented in freshwater—it will provoke controversy, as Hutchinson intends. The accent in the discussion of the biota is on the adaptation from the marine to the freshwater environment and on the geological history. The physiological problems of adaptation to freshwater are discussed and the genera illustrated are taken from the world fauna and many obscure forms are illustrated. There is a wealth of fascinating information here, but the reader has to wait until the later chapters for illustrations and discussions of the biology of the commoner plants and animals.

The second chapter is a very brief but valuable account of the terminology of lacustrine communities—the concept of a lake as a single biotope is not strictly adhered to in later chapters and some of the terms are little used. A fairly mathematical treatment of the hydromechanics of the plankton follows in which sinking rates and turbulence are considered. The next three chapters are devoted to the phytoplankton; first its nature and distribution, in which the major algal groups are discussed and related to some physiological parameters; secondly, the associations including multispecific equilibrium, diversity and ecological classification; moving finally to the seasonal succession in the last of these chapters. The examples are selected from a wide series of lake studies and these have been welded into a coherent story in which the author has not merely been content to report the work of others but has analysed it and synthesized it into a valuable discussion. The last three chapters are devoted to the animal components of the plankton. The nature and biology of the zooplankton are largely concerned with

Rotifera and Crustacea, while the non-photosynthetic in contrast to the photosynthetic Protists are shown to be of relatively less importance. The biology of these groups has been considered in its widest sense from life histories, ecology, seasonal succession, to vertical distribution. A mass of diffuse data is summarized, including valuable work on algae as food, a relatively neglected link in the productivity of lakes. This is followed by two rather special topics, vertical and horizontal distribution (especially of Cladocera) and cyclomorphosis. The latter is mainly concerned with rotifers (*Asplanchna*, *Keratella*) and Cladocera (*Daphnia*, *Bosmina*), but also deals with dinoflagellates (*Ceratium*) and, although a little out of place, the size changes in diatoms. As in the first volume, there is finally a list of symbols used in the book, an excellent bibliography and index, index of lakes (including latitude and longitude for most), index of organisms, and finally a general index. Summaries are provided at the end of each chapter and an elementary student may gain a considerable insight into limnology from these alone but would miss a wealth of thought-provoking material.

The production uses the same type and format as the first volume, but there are in this case rather more common mis-spellings, particularly in the captions to the figures, which are themselves excellently produced.

No review can hope to indicate the extensive coverage of literature and ideas, of scholarship and of effort which has gone into this volume. It is an expensive book and it is devoted partly to plants and partly to animals. I trust no serious student of limnology will be put off by either: to search the literature would be even more expensive of time, effort and money, and biological limnology is essentially a synthesis of both or rather all four kingdoms which, under water, assume equal importance; at least awareness of all is essential to good limnology.

F. E. ROUND

## RICE UP TO DATE

### Mechanization and the World's Rice

(Proceedings of a Conference to Support the International Rice Year 1966 of the FAO of the UN held Sept. 26–Oct. 1, 1966.) Pp. 163. (Warwickshire: Massey-Ferguson (Export), Ltd., 1967. Distributed throughout the world by Basil Blackwell, Oxford.) 63s.

RICE is the staple food of more than half the population of the world and most of it is still grown as a subsistence crop on very small holdings. There is urgent need to increase supplies, and in order to focus attention on the problems involved the Food and Agriculture Organization of the United Nations (FAO) made 1966 an International Rice Year within the Freedom from Hunger Campaign.

Available supplies may be increased by extending the area of rice grown, by increasing the yield of each acre, and by decreasing losses during subsequent storage and processing. Mechanization can help to achieve these objectives, and the conference held in 1966 discussed how best to introduce machinery; the types at present available were demonstrated.

The twenty-five papers describe various aspects of production, storage and processing; some speakers deal specifically with mechanization, others do not mention it at all. All contributors treated the subject generally and sometimes superficially. The presentation and technical content are likely to prove more valuable to those engaged in planning and administration than to the specialist.

The book is printed by direct reproduction of typescript in double columns without the type being justified and so presents an uneven appearance. The diagrams are all clear, and the several photographs of rice production and rice machinery improve the presentation. The report

is printed on good quality paper and is therefore pleasant to handle, although the paper-back binding appears somewhat flimsy.

I have no doubts that the conference was very valuable, but I doubt the value for money of the report.

J. K. R. GASSER

## REFERENCE TO LUMINESCENCE

### Luminescence of Inorganic Solids

By Paul Goldberg. Pp. xii + 765. (New York: Academic Press, Inc.; London: Academic Press, Inc. (London), Ltd., 1966.) 236s.

THIS book represents an attempt to survey inorganic luminescence in terms of a general introduction and eleven chapters on specific themes contributed by separate authors. Experience will have made readers painfully aware of the drawbacks of this treatment, but this volume indicates that a judicious editor can build up, instead of a chaos of fragmentation and repetition, a well-composed picture of the topic by prudent choice of authors and careful correlation of their contributions. In fact, Dr Goldberg has done much to free the field of luminescence from the siege mentality engendered in a topic which, in relation to theory, developed before its time, and which has often been stultified by an intractable technology.

The core of the book consists of articles on luminescence in halide, diamond and ZnS lattices, that is, those areas in which luminescence is in useful contact with other active areas of solid state physics. Oxygen-dominated phosphors are treated separately, and other sections deal with the materials problems of the development of lasers, and the luminescence of glasses and of thin films, providing some good surveys of the newer technical extensions of luminescence. There are two chapters on electroluminescence, one dealing with  $p-n$  junctions and the other with the less certain field of zinc sulphide. The use of electron spin resonance to study luminescence centres is admirably surveyed, and in the final chapter the different aspects of particle-excited luminescence, separated by historical accident, are unified.

The index in a book of this type is of great importance, but this one is, unfortunately, rather inadequate—for example, there is no cross-reference from “Optical Maser” to “Laser”. None the less, the book should serve well as both reference book and textbook for some time to come.

G. F. ALFREY

## THERMODYNAMICS AGAIN

### Thermodynamics

An Advanced Treatment for Chemists and Physicists. By E. A. Guggenheim. Fifth, revised edition. Pp. xxiii + 390. (Amsterdam: North-Holland Publishing Company, 1967.) 86s.

THIS edition, the fifth in eighteen years, has the same virtues of clarity, brevity and authority that marked its predecessors.

There is a new chapter of two pages on systems in motion according to the special theory of relativity. Here the problem of the temperature of a moving body—a problem that has given rise to recent correspondence and an editorial in *Nature*—is characteristically disposed of in one sentence: “There is no need to mention temperature and indeed the property of temperature will depend on its precise definition”.

Much of the rest of the book has been revised in detail. The discussion of critical phenomena and of transitions of higher order, however, is essentially unchanged, although powerful inequalities, discovered in the past four years, have rendered obsolete all discussions before 1965.

One striking innovation is the use of an unnamed symbol for the Helmholtz free-energy. It is formed by running together A and F. J. S. ROWLINSON

## SOLAR SYSTEM ASTRONOMY

### Moon and Planets

Edited by A. Dollfus. (A Session of the Seventh International Space Science Symposium held in Vienna on May 10-18, 1966.) (Sponsored by COSPAR and IAU.) Pp. 321+26 photographs. (Amsterdam: North-Holland Publishing Company, 1967.) 90s.

THE progress which space science has made during its first decade has astonished even some of its more optimistic proponents, and it has become difficult in these days of the information explosion for astronomers pursuing their work in extra-solar-system astronomy to keep abreast of developments in space science (apart from a few well-publicized glamorous discoveries). And in spite of the developments which have taken place, it must be recognized that our new knowledge is fragmentary, and that new questions are being asked faster than they can be answered. Many of us look forward to the day when it will be possible to publish an important textbook, with all its chapters fully integrated one with another, and covering the main aspects of planetary and lunar astronomy, with a full and adequate account of modern developments. Clearly, such a book, if written now, would be premature. We must therefore be grateful for the present volume. Its most valuable feature is undoubtedly a number of survey papers, which will be of interest to a wider audience than some of the individual contributions and abstracts. I single out for mention articles by G. P. Kuiper on the lunar surface and the US Ranger programme, by A. D. Kuzmin on the results of radio observations of the planets, by I. I. Shapiro on planetary radar astronomy, by O. W. Nicks on the Mariner IV results, by R. K. Sloan on the Mariner IV photographs of Mars, and by W. C. DeMarcus on the general theory of (the internal structure of the) planets. The volume is a required purchase for libraries of physics and astronomy because of these surveys, and the latter will be valuable as basic references for astrophysics and space science students until such a time as more integrated treatment of solar system astronomy becomes available.

R. H. GARSTANG

## QUANTUM THEORY OF FIELDS

### Lectures on Quantum Field Theory

By Paul A. M. Dirac. (Belfer Graduate School of Science Monograph Series, No. 3.) Pp. viii+151. (New York: Belfer Graduate School of Science, Yeshiva University, 1966. Distributed by Academic Press, New York and London.) 60s.

PROFESSOR DIRAC'S book, as its title and colloquial style suggest, is based on a lecture course given by him in the session 1963-64 at Yeshiva University, New York. This is not a textbook in the conventional sense: it is, rather, a critical essay in which the essayist describes lucidly his thoughts on the difficulties and illogicalities of the traditional approach to the quantum theory of fields; then in developing the theory of quantum electrodynamics he demonstrates just how he has come to terms with the problems he has raised.

The underlying philosophy of the book has already received considerable publicity<sup>1,2</sup>. Letters to *Nature*<sup>3,4</sup> on the subject of the first article indicate that the ideas put forward are not altogether uncontroversial.

The essential point which Professor Dirac makes is that, in the field theoretic context, "the Heisenberg

picture is a good picture and the Schrödinger picture is a bad picture and that the two pictures are not equivalent". The essence of this point is made explicit when a simple field theoretic model is analysed. Thereafter the author sets about the task of developing a quantum field theory (quantum electrodynamics) working entirely within the framework of the Heisenberg picture and avoiding any direct use of the Schrödinger picture. In any theory which does not admit Schrödinger wave functions the usual probabilistic interpretation of the theory must be abandoned. This problem is tackled by the author and a new basis of interpretation is suggested. Important in these new interpretative proposals is the normal ordering of operators and this, being deemed of physical significance, is taken over from work done in the Schrödinger picture. By developing quantum electrodynamics in the Heisenberg picture many but not all of the "illogical" infinities of the traditional approach are successfully eliminated; it is proposed that other infinities be removed by the introduction of cut-offs, and the arguments presented here seem to me plausible rather than strictly logical. Professor Dirac is careful to point out that each standpoint adopted is merely that which seems to him to be the best at the present stage of knowledge and that we must always be ready to alter our point of view in the light of new facts.

In this formulation there is no place for an *S*-matrix and it would have been interesting to have had Professor Dirac's evaluation of the extensive literature on *S*-matrix theory and other modern outgrowths of traditional field theory.

I am certain that *Lectures on Quantum Field Theory* will provide the serious student with most interesting and stimulating reading: the arguments are presented with great clarity and the layout (despite the absence of an index, which is largely compensated for by the paragraph titles) is good.

## MAN'S WORLD

### The Science of Society

An Introduction to Sociology. By Stephen Cotgrove. (The Minerva Series of Student's Handbooks, No. 19.) Pp. 310. (London: George Allen and Unwin, Ltd., 1967.) 40s. net.

THIS is an erudite, yet readable and easily assimilated, introductory textbook of sociology. Using the structure-function approach, in particular the "theories" and perspectives developed by Talcott Parsons, the author marshals a judicious mixture of British and American research findings into a text which both serves as an introduction to the elements of sociological analysis and offers the reader a description of contemporary British institutions. This is something of an achievement, for the "theoretical" frame of reference is not a simple one, and its exponents are not noted for clarity and simplicity in their prose style. The book differs from many introductory sociology textbooks by adopting the refreshing approach of assuming that its readers read other books. In particular it was pleasing to find that the author had dispensed with the traditional obeisance to the "Founding Fathers of Sociology" and settled for a discussion of what sociology is about today.

The work of Talcott Parsons has had a great influence on modern sociological teaching and research. Good textbooks using his frame of reference, however, have been rare. Those using it have made the mistake of forcing the material into the conceptual framework in the mistaken belief that it is a verified theory. While Professor Cotgrove closely adheres to the scheme he does not fall into

this trap; consequently he utilizes other theoretical perspectives, particularly "symbolic interactionism" and "social action" theory, when they appear to offer better explanations.

The material is thus organized on the Parsonian assumption that every social system has four functional problems to solve: (a) latent pattern maintenance and tension management dealt with in chapters on the "Family" and the "Educational System"; (b) adaptation to the environment discussed in a chapter on the "Economic System"; (c) goal attainment handled in a chapter on the "Political System"; and (d) integration covered by a discussion of "Belief Systems".

The chapter on education is a particularly good one reflecting Professor Cotgrove's interest in technical education. A passage in the section on politics which states that since the passing of the 1927 Trade Union Act union members "contract-in" to political funds needs amending. The 1946 Act repealed the 1927 Act, thus restoring the 1913 Act, which means that those who do not wish to pay the levy must now "contract-out". The final chapters are given over to a discussion of social processes—"Stratification", "Organizations", and "Deviance, Disorganization and Change".

The undoubted merit of the Parsonian system is its logical coherence and plausibility in explaining certain features of social life. The book is therefore well organized and logically developed. Professor Cotgrove thus capitalizes on the strengths of Parsonian "theory". He also endeavours to avoid its weaknesses. Here he is hampered by the nature of the framework. In particular the notion of society as a homeostatic system with its parts adjusting to each other to achieve equilibrium is implicit in the analysis. From the student's point of view this helps to order and simplify the apparent complexity of social phenomena at the expense of explaining the pervasiveness of conflict in society. Professor Cotgrove acknowledges Dahrendorf's criticism of Parson's work; however, he presents conflict as a second level interaction coming into operation only when homeostasis breaks down. Further, conflict is not adequately defined by contrasting it to other forms of interaction such as competition and co-operation.

An introductory text can serve several functions and must, by necessity, be selective. Criticism of the selection is therefore rather arbitrary. However, I feel that a discussion of the methods of social research and the problems of validity and reliability of techniques would have been useful. It would then have been possible to include more quantitative data in the text, giving the student an opportunity to appraise the research findings more critically.

With its comprehensive bibliographies and discussion topics at the end of each chapter the book would be a good introductory text for sixth forms of grammar schools, for colleges of education, and for first year undergraduate courses.

F. G. COOK

## OBITUARIES

### Professor R. A. L. Black

ROBERT ALASTAIR LUCIEN BLACK, professor of mining and head of the department of mining and mineral technology at the Imperial College of Science and Technology, died suddenly in London on June 22. He was 46.

Black was educated at Stowe and at Imperial College, but his university course was interrupted by the war. From 1940 he served with the air branch of the Royal Navy, first in the Indian Ocean area and then in the Middle East and Malta, where he was awarded the Distinguished Service Cross in 1943. He was demobilized in

1945 as lieutenant (A), RNVR, and immediately returned to the Royal School of Mines to resume his education. A brilliant student, he graduated with first class honours in mining the following year, having carried off three prizes and two medals.

The next seventeen years of his life were spent in South Africa where, in the Witwatersrand gold fields, he first gained practical experience of the engineering and management problems associated with complex mining operations. In very deep mining, ventilation and the structural control of rock movement constitute the major technical difficulties. By the time he was 34, Black had made valuable contributions in both these fields and had gained practical experience up to the level of underground manager. He was therefore a logical choice to be head of the department of mining engineering at the University of the Witwatersrand when the position became vacant in 1955.

He entered academic life at a time when the mineral industry was beginning to face two important and conflicting trends. The first was the application of advanced scientific and engineering developments to the increasingly complex problems of large-scale mining which, together with the introduction of new techniques of management and production engineering, constituted a revolution in an industry which hitherto had been based largely on experience, hard work and common sense. The second was the alarming deterioration of mining schools in the English-speaking world. Black's last twelve years were devoted to advancing the first trend and arresting the second.

At the University of the Witwatersrand he reorganized the undergraduate syllabus on modern, science-based lines and established a new postgraduate school and research unit. The position of consultant to the Transvaal and Orange Free State Chamber of Mines is concomitant with that of professor of mining engineering, and this enabled Black both to enlarge his experience and to put his ideas into practice. In the same period he served as dean of the faculty of engineering, as dean of the university residence, as director of the government miners training schools and as a member of the government commission of enquiry into the methods of training for engineering in South Africa.

A liberal and humane man with a strong sense of justice his distress at political developments conflicted with the loyalty he felt for his adopted country. This dilemma was happily resolved in 1963 when he was asked to return to his old college as professor of mining—an invitation which he could not refuse. He applied himself to his new tasks with characteristic energy and effect; the undergraduate syllabus was revised, postgraduate teaching and research were expanded and, on his initiative, an interdepartmental research group on rock mechanics was established with civil engineering and geology.

He had widespread contacts throughout the mining world and his reputation, both as an engineer and as an educator, was international. His technical writing—mainly on rock mechanics, environmental engineering and mining education—was highly regarded and he had advised on important mining operations and lectured on his speciality in Africa, Australia, Europe and in both North and South America. He was a member of council of the Institution of Mining and Metallurgy and played an active part in the development of the Council of Engineering Institutions.

Black was an unpretentious man with no vanity, and disliked formality. His exceptional intelligence and ability provided an authority that he did not need to stress and his personality was sympathetic and entirely unaggressive. He never pressed a point unless he believed that it was right and fair, but then his argument was convincing and his enthusiasm infectious. His influence, both as a professional engineer and as a teacher, was great and his untimely death is a sad and irreparable loss to the mineral industry and to his many friends.

M. G. FLEMING

## University News :

**Belfast**  
DR P. G. BURKE has been appointed to the chair of mathematical physics.

## Manchester

DR K. W. BAGNALL, at present senior principal scientific officer at the Atomic Energy Research Establishment, Harwell, has been appointed to the chair of inorganic chemistry, in succession to Professor J. Lewis, who has been appointed to the chair of chemistry in University College, London; Professor D. B. G. Edwards, professor of computer engineering in the University, has been appointed to the I.C.T. chair of computer engineering, and Mr A. J. Morton, at present group services engineer of the Southern Projects Group in the Central Electricity Generating Board, has been appointed to an additional chair of engineering. Mr D. L. Burn has been appointed visiting professor of economics for one year from October 1.

## Appointments

DR E. PASSAGLIA, formerly chief of the Polymer Physics Section, has been appointed chief of the Metallurgy Division of the US National Bureau of Standards.

## Meetings

PURE and Applied Chemistry, September 4-10, Prague (The Chairman, Organizing Committee, XXIst International Congress of Pure and Applied Chemistry, POB 139, Praha 6—Dejvice).

INSTRUMENTATION for Engineers, September 4-October 6, University of Sheffield (Professor W. A. Tuplin, Department of Applied Mechanics, University of Sheffield, St. George's Square, Sheffield, 1).

PHYSICS of Quasars, September 5-7, University of Manchester (The Meetings Officer, The Institute of Physics and the Physical Society, 47 Belgrave Square, London, SW1).

SOLID State Devices, September 5-8, Manchester Institute of Science and Technology (The Meetings Officer, The Institute of Physics and the Physical Society, 47 Belgrave Square, London, SW1).

II-VI Semiconducting Compounds, September 6-8, Brown University, Providence, Rhode Island (D. W. Langer, Conference Secretary, Aerospace Research Laboratories, Wright-Patterson AFB, Ohio).

MOLECULAR Spectroscopy, September 10-15, Madrid (IXth European Congress on Molecular Spectroscopy, Serrano, 117, Madrid).

AGRICULTURAL Engineering, September 11-14, National College of Agricultural Engineering, Silsoe, Bedfordshire (Honorary Organizing Secretary, Agricultural Engineering Symposium, The Institute of Agricultural Engineers, Penn Place, Rickmansworth, Herts).

CARBONIFEROUS Stratigraphy and Geology, September 11-16, Sheffield (Dr A. W. Woodland, Secretary-General, Geological Survey Office, Ring Road, Halton, Leeds 15).

8TH ANNUAL Scientific Meeting of the Anglo German Medical Society, September 14-16, Glasgow (Professor W. A. Mackey, Royal Infirmary, Glasgow, C4).

CREATIVE Engineering Design, September 11-16, Queen Mary College (Department of Mechanical Engineering, Queen Mary College, Mile End Road, London, E1).

QUANTITATIVE Methods in Reflected-light Microscopy, September 19-23, Cambridge (Mr G. A. Kingston, Department of Geology, Imperial College, London, SW7).

SURFACE Phenomena of Metals, September 20-22, Brunel University, London (Professor K. S. W. Sing, Department of Chemistry, Brunel University, Woodlands Avenue, Acton, London, W3).

USE of Radioactive Isotopes in Pharmacology, September 20-23, Geneva (Professor B. Glasson, Pavillon des Isotopes, 20 bd d'Yvoy, 1211 Genève).

MASS Spectrometry, September 25-29, Technische Universität, West Berlin (The Institute of Petroleum, 61 New Cavendish Street, London, W1).

DATAFAIR 67, September 25-29, University of Southampton (The British Computer Society, 23 Dorset Square, London, NW1).

MICROBIOLOGICAL Chemistry, September 26-28, Sheffield (Dr E. Haslam, Department of Chemistry, The University, Sheffield, 10).

ERRATUM. In the note "Shape of Universities" (*Nature*, 214, 865; 1967) it should have been stated that Sir Eric Ashby delivered the Queen's Lecture at the Free University of Berlin, not at the University of Belfast.

ERRATUM. In Table 1 of the article "Tale of Two Countries" (*Nature*, 215, 9; 1967) the figures for expenditure as a percentage of GNP have been interchanged. They should read United Kingdom, 2.3; West Germany, 1.3.

CORRIGENDUM. In the communication "Photosensitized Oxidation of Carbon Monoxide on Semi-conductors supported on Silver" (*Nature*, 215, 152; 1967) the values for activation energies should be double the values given in Table 1, with the exception of the activation energies for Ag.

# CORRESPONDENCE

## Equipment Grants

SIR,—Your editorial, "Fighting the Wrong Battle" (*Nature*, 215, 337; 1967)—why such war-like terms?—is misleading in a number of important respects. As Sir Cyril Hinshelwood and his colleagues claimed, it is true that the University Grants Committee dishonoured firm pledges of monies for the equipment of new buildings, and your figure of a deficit of £15.5 million against previous promises confirms this claim. Other requirements were with, or going to, the UGC and these have to be added to this deficit. What you also do not note is that, without this money, science teaching departments will have to open this October without their planned complement of apparatus. Much effort in planning courses, preparing equipment schedules and so forth has been vitiated, and scratch arrangements will have to be made, very late in the day, to the extent that universities are able, and willing, to borrow funds for this purpose. Academic policy is being settled by finance. Further, commitments were made to new staff as to their facilities and equipment, and this, too, is in the melting pot. No new department, in old or new university, can feel confident about the future after this galling experience.

You also say that the UGC's proposed new system "means everyone will be better off". Until we know what this system is, no one can pronounce on it! Two things are clear. A simple, *per capita* scheme will not meet the very different needs of all our universities, since most are at different stages of equipment, and re-equipment, for science teaching and research. Until we know what adjustments are to be made for this, and what the specific allocation of funds will be, all planning for the future involves too many uncertainties to be faced with confidence. The student population, as you note, is growing; the question is: will the equipment and staff be there so that it can be properly taught?

Yours faithfully,

JAMES H. SANG

Biology Building,  
University of Sussex,  
Falmer, Brighton.

## APPOINTMENTS VACANT

APPLICATIONS are invited for the following appointments on or before the dates mentioned:

**RESEARCH ASSISTANT IN THE DEPARTMENT OF ZOOLOGY** to work with Dr K. R. Ashby on problems connected with the development of the reproductive system in fish and the effects produced by treatment with sex hormones during early life—The Registrar and Secretary, University of Durham, Old Shire Hall, Durham (August 9).

**LECTURER** (with a first- or second-class honours degree in psychology and research and/or industrial experience) in **PSYCHOLOGY** at Durham University Business School—The Registrar and Secretary, Durham University, Old Shire Hall, Durham (August 11).

**ASSISTANT LECTURER** (preferably with one of the following fields of interest: bacteriology, microbial genetics, whole-plant physiology, physiological ecology, or experimental mycology) in **BOTANY**—The Secretary, Birkbeck College (University of London), Malet Street, London, W.C.1 (August 14).

**TUTOR/SENIOR TUTOR and LECTURER/SENIOR LECTURER in BIOLOGY, GEOGRAPHY, HISTORY OF SCIENCE and TECHNOLOGY, MATHEMATICS** at the University of Papua and New Guinea—The Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1; or The Registrar, University of Papua and New Guinea, P.O. Box 1144, Boroko, T.F.N.G. (August 15).

**EXPERIMENTAL OFFICER or SENIOR EXPERIMENTAL OFFICER** in the DEPARTMENTS OF BOTANY and ZOOLOGY to assist in the running of an **ELECTRON MICROSCOPE UNIT**—The Registrar, The University, Manchester, 13, quoting Ref. 117/67/Na (August 16).

**ALGOLIST/PLANT PHYSIOLOGIST** (with a first- or good second-class honours degree in botany with a special interest in primary production or plant physiology; but candidates with a degree in biochemistry or an allied subject with an interest in, or knowledge of, fresh water algae will also be considered) to study primary production and factors limiting the production of phytoplankton at Loch Leven as part of an International Biological Programme Study—The Nature Conservancy, 12 Hope Terrace, Edinburgh, 9 (August 18).

**EXPERIMENTAL OFFICER** in the DEPARTMENT OF BOTANY for duties which will include assistance in the teaching of techniques in microscopy, including electron microscopy and in research—The Secretary, Academic Council, The Queen's University, Belfast, Northern Ireland (August 18).

**LECTURER** (with a good honours degree and/or a higher degree in psychology) in **EDUCATIONAL PSYCHOLOGY** in the DEPARTMENT OF EDUCATION—The Registrar, University College of North Wales, Bangor, North Wales (August 18).

**RESEARCH ASSISTANT** (preferably with an interest in physiological ecology) in the DEPARTMENT OF BOTANY, to work with Dr D. J. Boatman on aspects of peat bog development on the Silver Flowe Nature Reserve—The Registrar, The University, Hull (August 19).

**SENIOR RESEARCH OFFICER** (with research experience in some branch of engineering) in the DEPARTMENT OF APPLIED MATHEMATICS for research in Rheology—The Registrar, University College of Wales, Aberystwyth (August 19).

**CHIEF TECHNICIAN** (botanical knowledge helpful but not essential) in the SCHOOL OF PLANT BIOLOGY—The Registrar, University College of North Wales, Bangor, North Wales (August 20).

**BOTANIST** (with a good honours degree and preferably postgraduate research experience) for research on the growth and phenology of arctic-alpine vegetation in the Cairngorms and in Iceland—The Nature Conservancy Unit of Grouse and Moorland Ecology, Blackhall Buildings, Banochry, Kincardineshire (August 21).

**HORTICULTURAL ADVISERS** (with a degree in horticulture or a closely related subject; or National Diploma in Horticulture (sections I to VI); or equivalent or higher qualifications) with the National Agricultural Advisory Service, Ministry of Agriculture, Fisheries and Food (at least 13 posts)—The Civil Service Commission, Savile Row, London, W.1, quoting Ref. 345/67 (August 21).

**SENIOR LECTURER and a LECTURER in MATHEMATICS** at the University College of Rhodesia—The Inter-University Council, 33 Bedford Place, London, W.C.1 (August 21).

**SENIOR LECTURER in VETERINARY MEDICINE** at the University of Queensland, Australia—The Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (London and Brisbane, August 25).

**ASSISTANT LECTURER or LECTURER in COMPUTATION** in the DEPARTMENT OF MATHEMATICS—The Deputy Secretary, The University, Southampton (August 28).

**SCIENTIFIC OFFICER/SENIOR SCIENTIFIC OFFICER** (with a degree in microbiology or in biochemistry or chemistry with experience in microbiology) in the MICROBIOLOGY DEPARTMENT to be concerned with the extension of work on the nitrogen metabolism of micro-organisms in rumen contents using stable isotopes of N and <sup>14</sup>C and <sup>3</sup>H—The Secretary, Rowett Research Institute, Bucksburn, Aberdeen, Scotland (August 28).

**SCIENTIFIC OFFICER** (with a first- or upper second-class honours degree in mathematics with statistics, or a diploma in statistics) in the STATISTICS SECTION for duties mainly concerned with the design and analysis of field and laboratory experiments, and providing a statistical and data processing service—The Secretary, The Macaulay Institute for Soil Research, Craigiebuckler, Aberdeen (August 28).

**SENIOR LECTURER, LECTURER or JUNIOR LECTURER in GEOGRAPHY, PHILOSOPHY, PSYCHOLOGY/SOCIOLOGY, and PURE MATHEMATICS** at the University of Waikato, Hamilton, New Zealand—The Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (New Zealand and London, August 28).

**BIOMETRICIAN** (with an honours or postgraduate degree in, or including, mathematical statistics, and some experience in applied statistics, preferably in biological science) at the Forest Research Institute, Rotorua, New Zealand, to be in charge of the Biometrics Section and act as statistical consultant to officers engaged in the full range of forestry research covering production, protection and utilization, and to carry out statistical analysis and undertake research into statistical methods—The High Commissioner for New Zealand, New Zealand House, Haymarket, London, S.W.1, quoting Ref. B13/8/35/2014 (August 31).

**ELECTRON MICROSCOPIST (Experimental Officer)** (with a university degree or equivalent and experience in the maintenance and use of modern electron microscopes) in the DEPARTMENT OF METALLURGY—The Registrar, University of Sheffield, Sheffield (August 31).

**HEAD** (honours graduate in mathematics, qualifications in statistics and an interest in biological problems) of the STATISTICS SECTION of the DEPARTMENT OF AGRICULTURE and HORTICULTURE, Long Ashton Research Station—The Registrar, Senate House, The University, Bristol 2 (August 31).

**LECTURER in PHYSICS** to pursue research in experimental high energy physics—The Registrar, The University, Manchester, 13, quoting Ref. 119/67 (August 31).

**LECTURER or ASSISTANT LECTURER in APPLIED MATHEMATICS**—The Registrar, The University, Senate House, Bristol, 2 (August 31).

**ASSISTANT/ASSOCIATE PROFESSORS** (with experience in solid mechanics, fluid mechanics and thermodynamics) in **MECHANICAL ENGINEERING**—Dr D. H. Norrie, Head, Department of Mechanical Engineering, University of Calgary, Calgary, Alberta, Canada.

**BIOCHEMIST** (basic grade) for research into lipoprotein metabolism in children—Professor O. H. Wolff, Institute of Child Health, The Hospital for Sick Children, Great Ormond Street, London, W.C.1.

**BIOCHEMIST or MICROBIOLOGIST, SENIOR SCIENTIFIC OFFICER or SCIENTIFIC OFFICER** (preferably with experience of immunology) in the BACTERIOLOGY DEPARTMENT, to join a group working on natural defence mechanisms of the udder against mastitic pathogens, in particular staphylococci—The Secretary, National Institute for Research in Dairying (University of Reading), Shinfield, Reading, Berkshire, quoting Ref. 67/25.

**BIOCHEMIST** (preferably postdoctoral) to work on physical and chemical properties of the proteins of the lens with reference to formation of lens opacities—Dr A. Pirie, Nuffield Laboratory of Ophthalmology, Walton Street, Oxford.

**ENGINEERS or PHYSICISTS** for work on advanced electro-optical input devices—The Director, Clinical Effects of Radiation Research Unit, M.R.C., c/o 107 Sydney Street, London, S.W.3.

**GRADUATE RESEARCH ASSISTANT** in the Regional Rheumatism Research Centre to work with medical staff—The Administrative Officer, Stoke Mandeville Hospital, Aylesbury, Bucks.

**GRADUATE RESEARCH ASSISTANT** (preferably with experience of, or a keen interest in, modern techniques of analytical biochemistry) in **TOXICOLOGY**, to join in chemical studies of drug action, in association with the Poisoning Treatment Centre, Edinburgh Royal Infirmary—Dr S. S. Brown, University Department of Clinical Chemistry, Royal Infirmary, Edinburgh, 8.

**GRADUATE** (with a good honours degree in chemistry or equivalent qualifications) at the Queen Elizabeth Hospital (Institute of Child Health), Hackney Road, London, E.2, to assist in research on mucopolysaccharides in disease—The Group Secretary, Hackney, and Queen Elizabeth Group Hospital Management Committee, Administrative Offices, Hackney Hospital, London, E.9.

**HIGHER TECHNICAL ASSISTANT** (with sound electronics experience and an interest in research) in the CRYSTALLOGRAPHY GROUP to assist with the maintenance and operation of advanced X-ray diffraction equipment and the work of the group generally—The Superintendent, University Chemical Laboratory, Lensfield Road, Cambridge.

**HOSPITAL BIOCHEMIST** (probationary grade) (recent graduate in chemistry or biochemistry) in the CHEMICAL PATHOLOGY DEPARTMENT, St. Charles Hospital, Ladbroke Grove, London, W.10—The Director of Pathology, c/o Paddington Group Hospital Management Committee, Harrow Road, London, W.9.

**JOHNSON and JOHNSON RESEARCH FELLOW** for work on wound healing or transplantation—Mr H. Cooke, Personnel Officer, Royal College of Surgeons of England, Lincoln's Inn Fields, London, W.C.2.

**LECTURER or ASSISTANT LECTURER** (with an interest in economic or structural geology) in **METAMORPHIC PETROLOGY** in the DEPARTMENT OF GEOLOGY, Fourah Bay College, The University of Sierra Leone—The Inter-University Council, 33 Bedford Place, London, W.C.1.

**LECTURER** (with a special interest in optical instrumentation, including the design of instruments or in modern experimental optics, and preferably experience in the optical industry) to undertake postgraduate teaching and research in the Applied Optics Section of the PHYSICS DEPARTMENT—Professor W. D. Wright, Applied Optics Section, Physics Department, Imperial College, London, S.W.7.

**MICROBIOLOGIST** (graduate) in the DEPARTMENT OF CLINICAL PATHOLOGY—The Assistant Secretary, University College Hospital, Gower Street, London, W.C.1.

**POSTDOCTORAL FELLOW** (preferably with experience in mass spectrometry) in the PROCTOR DEPARTMENT OF FOOD and LEATHER SCIENCE, to undertake research into the chemical basis of the aroma and flavour of foodstuffs, using gas chromatography for the separation of volatile food components and mass and infrared spectrometry for their identification—Dr H. E. Nursten, The University, Leeds, 2.

**RESEARCH ASSISTANT, BIOCHEMIST or VETERINARY PATHOLOGIST** (preferably with postgraduate research experience and/or a higher degree) in the IMMUNOLOGY CANCER RESEARCH UNIT—The Registrar, University of Liverpool, Liverpool, 3, quoting Ref. RV/100/N.

**RESEARCH ASSISTANT** (with a good honours degree, preferably in genetics) for work on the biology of the large bulb fly, *Merodon equestris*, and the genetics of its mimetic polymorphism—W. D. Hamilton, Esq., Imperial College, Silwood Park, Sunninghill, Ascot, Berkshire.

**RESEARCH ASSISTANT** (with an honours degree in botany or agricultural science and a special interest in plant pathology) for work on potato tuber diseases—The Secretary, Edinburgh School of Agriculture, West Mains Road, Edinburgh.

**RESEARCH ASSISTANTS** (preferably with a Ph.D. degree in physics or engineering) at the Central Research Station of the International Flame Research Foundation, Ijmuiden, Holland, to join a small team of postdoctoral investigators to work on problems of combustion physics, in particular aerodynamics and heat transfer aspects of turbulent flames—Professor J. M. Beer, Department of Fuel Technology and Chemical Engineering, University of Sheffield, Mappin Street, Sheffield, 1.

**RESEARCH ASSISTANTS** (with a first- or second-class honours degree in mathematics or statistics) in **MATHEMATICS**—Head of the Department of Mathematics, Northern Polytechnic, Holloway, London, N.7.

**SCIENTIFIC OFFICER** (basic grade) (with an honours degree in science) for the MYCOLOGY RESEARCH LABORATORY—Miss P. Duncan, Secretary, Bernhard Baron Memorial Research Laboratories, Queen Charlotte's Maternity Hospital, Goldhawk Road, London, W.6.

**SENIOR MEDICAL PHOTOGRAPHER and HEAD** (with appropriate professional qualifications and experience of running a small department and the supervision of staff) of the MEDICAL ILLUSTRATION DEPARTMENT—The Secretary, Institute of Ophthalmology (University of London), Judd Street, London, W.C.1.

**SENIOR TECHNICIAN** (Grade II) and a **TECHNICIAN** (Grade III) for an expanding DEPARTMENT OF MICROBIOLOGY concerned with both teaching and research—The Assistant Bursar (Personnel), The University, Reading, quoting Ref. T. 23.

**S.R.C. INDUSTRIAL RESEARCH STUDENT** (graduate in biochemistry, biology, botany or chemistry) to work on the translocation of a number of biologically important compounds in plants—Prof. N. F. Robertson, Department of Botany, The University, Hull.

**TRAINEE ELECTROENCEPHALOGRAPHY TECHNICIAN** (with G.C.E. "O" levels in English language, mathematics and a science subject, an ability to

deal with people as well as some interest in electronic apparatus)—The Secretary, Goodmayes Hospital, Barley Lane, Goodmayes, Ilford, Essex.  
**VOKES RESEARCH FELLOW** (graduate in engineering, chemistry or physics) in the DEPARTMENT OF MECHANICAL ENGINEERING—The Deputy Secretary, The University, Southampton.

## HOW TO BUY NATURE

Volumes start in January, April, July and October, but subscriptions may begin with any issue.

The direct postal price per subscription for one or two copies of NATURE each week is:

**\*12 MONTHS** (52 issues and 4 indexes)

Great Britain and Eire.....**£14.0.0** each  
 United States of America.....(by air freight).....**\$44** each  
 Canada.....(by air freight).....**\$47.80** each  
 Elsewhere overseas by surface mail.....**£13.15.0** each

(Charge for delivery by air mail on application)

\*Shorter periods *pro rata*. (Minimum three months.)

### MULTIPLE SUBSCRIPTIONS

For subscribers who take more than two copies of NATURE each week these reduced annual rates are offered:

**12 MONTHS** (52 issues and 4 indexes)

Number of Copies	G.B. & Eire	U.S.A. (by air freight)	Canada (by air freight)	Elsewhere (surface mail)
	Each	Each	Each	Each
3-5	<b>£13.10.0</b>	<b>\$42</b>	<b>\$46.00</b>	<b>£13.10.0</b>
6-11	<b>£12.15.0</b>	<b>\$40</b>	<b>\$43.60</b>	<b>£12.15.0</b>
12 or more	<b>£12.0.0</b>	<b>\$38</b>	<b>\$41.70</b>	<b>£12.0.0</b>

Multiple subscriptions must run concurrently. Every copy will be posted separately, and for speed of delivery each subscription can be addressed to a different individual, or department at the same address. (ZIP essential for U.S.A.)

## Theory and Practice of the Evaluation of Measurements

L. JÁNOSSY

This is a book for physicists and all who are concerned with experimental work. The author gives a careful analysis of the principles to be employed in evaluating the results of measurements and illustrates them with examples taken from actual laboratory material. 72 text figures  
35 net

*International Series of Monographs on Physics*

## Dynamical Theories of Brownian Motion

EDWARD NELSON

The author reviews the theories put forward by Einstein and others to account for the phenomenon of Brownian motion. His conjecture is that a certain portion of current physical theory, while mathematically consistent, is physically wrong, and he proposes an alternative theory.

### APPOINTMENTS VACANT

#### UNIVERSITY OF LIVERPOOL

##### BIOCHEMIST OR VETERINARY PATHOLOGIST

Applications are invited for the post of Research Assistant in the Immunology Cancer Research Unit. Postgraduate research experience and/or higher degree desirable, but not essential. Experience in immunological techniques, protein and enzyme chemistry and/or tumour transplantation in pure strain animals an advantage, but not essential.

The successful candidate will be a member of a team researching into fundamental immunological aspects of cancer in animals and man. Excellent research opportunities in well equipped new laboratories. Salary range £1,100 to £1,500 per annum (plus F.S.S.U.) according to qualifications and experience.

Applications, with curriculum vitae, and names of three referees, to the Registrar, University of Liverpool, Liverpool 3. Please quote Ref.: RV/100/N. (405)

#### PRINCIPAL

#### SCHOOL OF MEDICAL LABORATORY TECHNOLOGY

##### FEDERAL UNIVERSITY OF MINAS GERAIS BRAZIL

Applications are invited for appointment as Principal for this new School of Laboratory Technology, which is to be developed with British assistance at the Federal University of Minas Gerais, Belo Horizonte, Brazil.

Candidates, who must be nationals of the United Kingdom or Republic of Ireland, should be science graduates with wide industrial and technical college experience, preferably including responsibility for laboratory technician courses. Knowledge of Portuguese desirable but not essential.

Appointment on 3-year contract. Salary in range £3,700 to £4,000 per annum plus tax-free overseas service allowance £625 to £1,105 according to domestic circumstances. Free passages and accommodation. Education allowances.

Further information and application forms from the Council for Technical Education and Training for Overseas Countries, Eland House, Stag Place, London, S.W.1. Please quote TET/BRZ/12. Closing date for receipt of applications August 21, 1967. (499)

### Technicians

I.M.L.T. qualifications or H.N.C. (Applied Biology) for Bio-Chemical, Bacteriological, Haematological, Histological, virological posts in hospitals, industry, and research.—Miss J. R. Horton, G.K. Bureau Ltd., 196 Oxford Street, W.1. MUS 5858. (351)

## NEW DRUG RESEARCH

Have you had Experience  
or are you interested in any  
of these topics?

#### SYNTHESIS

*Amino Acids  
Peptides  
Heterocyclics  
Sulphur Chemistry*

#### ANALYSIS

*Analysis of Drugs  
Autoanalytical Techniques  
Elemental Analysis  
Chromatographic Techniques*

#### BIOLOGICAL EVALUATION

*Bioassay Techniques  
Toxicology and Pharmacology of Drugs  
Histology*

OUR AIMS: We are interested in synthesising new compounds that might be usefully employed in the control and correction of metabolic disorders.

OUR NEEDS: An expansion of our research activities has created several vacancies for *organic chemists* and *analysts, biologists, physiologists, and pharmacologists*, within the new research laboratories of Horlicks Pharmaceuticals Limited.

OUR LOCATION: The laboratories are situated in the delightful countryside of rural Berkshire adjacent to Windsor Great Park. They offer facilities and a working environment that are compatible with creative research work.

WE WELCOME: Application for these posts both from graduates with 1-2 years' experience and those recently qualified with a first or second-class Honours. Applicants are invited to write to:

**The Personnel Manager,  
Horlicks Pharmaceuticals Limited,  
Orchard Lea, Winkfield, Windsor,  
Berkshire.  
Telephone Number: Winkfield Row 2963**

(301)

## DIRECTOR

### Biomedical Engineering Department

The Ottawa Civic Hospital as a large and important University affiliated Institution requires a specialist in the field of biomedical engineering to become head of a new department to be established.

The Director will be responsible for a hospital-wide planning and development programme relative to biomedical engineering, including the provision of consulting, advisory and service functions as well as participation in clinical research projects and teaching programmes.

Applications are invited from candidates with an advanced academic standing (M.D. or Ph.D. level) and current knowledge and experience in biomedical engineering.

Attractive salary and fringe benefits commensurate with qualifications and experience.

**The Executive Director,  
Ottawa Civic Hospital,  
1053 Carling Avenue,  
Ottawa 3, Ontario, Canada.**

# opportunities in agriculture overseas

*General agriculturists and agricultural specialists of many kinds are frequently required in the effort to match the large demand from the developing countries. The vacancies advertised below are a selection from the many openings which exist now. While they are being filled, other vacancies are arising.*

*Salaries within the ranges quoted are assessed on qualifications and experience; and the terms of most appointments include free or subsidised accommodation, education grants, family passages, good leave on full pay, etc.*

*Most appointments are limited to nationals of the United Kingdom or the Republic of Ireland who are normally resident in those countries.*

## **BOTSWANA**

### **Agricultural Officer (Headquarters)**

RC 213/19/03

Duties: To assist the Director and Deputy Director of Agriculture in the administration of the Department of Agriculture.

Qualifications and terms: A degree in Agriculture with several years experience of administration at Provincial or territorial level. Salary £1,284 to £2,556 a year plus gratuity of 25%. Two to three year contract.

## **BOLIVIA**

### **Head of the British Tropical Agricultural Mission in Bolivia and General Adviser on Tropical Agriculture, to the Government of Bolivia**

RC 213/22/01

Duties: To lead a team of agricultural experts who would advise on the development of tropical and sub-tropical areas of Bolivia.

Qualifications and terms: A degree in Agriculture, preferably with Honours, plus wide experience in and responsibility for agricultural administration. Diploma in Tropical Agriculture, or other such recognized qualification, desirable. Salary £4,500 to £5,000, subject to British Income Tax, plus a variable non-taxable overseas allowance currently payable at £405 (Single) £780 (Married Unaccompanied) £965 (Married Accompanied), plus entertainment allowance of £250 p.a. Contract for two tours of 18 months.

## **FIJI**

### **Plant Breeder (Rice)**

RC 213/62/01

Duties: To assist with rice research programme and trials on other crops including varieties for wet and dry land, fertilizers, population studies and rotations.

Qualifications and terms: A degree in Botany, Agriculture or an allied subject and experience of rice breeding or research. Salary £1,208 to £2,414 a year plus 25% gratuity. 2½ to 3 year contract.

## **GAMBIA**

### **Agronomist**

RC 213/68/02

Duties: To design, carry out, supervise and analyse all agronomic experimentation on various crops; to make recommendations for the extension service and to investigate suitable crop rotations.

Qualifications and terms: A degree in Agriculture, preferably honours, with post-graduate training or experience in field experimentation. At least five years experience of tropical crops is essential. Salary £1,980 to £2,224 a year plus 25% gratuity. Contract two tours of 15 to 18 months.

### **Agricultural Officer**

RC 213/68/02

Duties: To carry out general extension work, including particularly oil palm nursery and plantation practices, to supervise mixed farming centres and to administer and supervise main Agricultural Station. Limited touring.

Qualifications and terms: A degree in agriculture with experience in general extension and mixed farming. Salary £1,140 to £2,224 a year plus 25% gratuity. 18 to 24 months contract.

## **KENYA**

### **Agricultural Economist**

RC 213/95/06

Duties: To advise the Ministry of Economic Planning and Development on matters connected with land settlement, livestock development, agricultural co-operatives, credit and targets.

Qualifications and terms: A degree in Agriculture with post-graduate qualifications in Agricultural Economics. A knowledge of agricultural problems in a developing country and experience in East Africa is desirable. Salary £2,000 to £3,000 a year, subject to British income tax, plus a variable tax-free overseas allowance currently payable at the rate of £260 to £915 a year depending on marital status. Contract 2 years.

## **MALAWI**

### **Soil Surveyor**

RC 213/134/04

Duties: To set up a soil survey section in the Department of Agriculture to undertake surveys for development projects; and later to train Malawian graduates to take full responsibility.

Qualifications and terms: Candidates must be qualified agriculturists with appropriate post-graduate experience. Salary £1,485 to £2,600 a year plus 25% tax-free gratuity. A supplement of £100 a year is also payable direct to an officer's bank account outside Malawi and Rhodesia. Contract 2 to 3 years.

## **TANZANIA**

### **Agricultural Officers**

RC 213/267/06

Duties: To plan clearing and conservation works by means of crawler tractor units; to supervise junior technical staff; to give advice on management to dairy farms and ranching associations; and to initiate policy and programmes for agricultural development.

Qualifications and terms: A degree in Agriculture. A knowledge of Swahili and experience in tropical agriculture is desirable. Salary £1,329 to £2,757 a year plus 25% gratuity. Contract 21 to 27 months.

## **THAILAND**

### **Agricultural Economist**

RC 213/175/04

Duties: To investigate and advise on farming systems and management, and on commodity marketing for the new Cotton Farm Development Centre.

Qualifications and terms: A degree and considerable experience of farm management studies and the economics of peasant farming. Salary £2,500 to £3,000 a year, subject to British income tax, plus a variable non-taxable overseas allowance currently payable at the rate of £695 to £1,430 a year depending on marital status. 3 year contract in the first instance.

## **ZAMBIA**

### **Ecologist**

RC 213/132/08

Duties: To acquire a working knowledge of the flora of Zambia, to carry out research on bush encroachment of grazing areas, and to assist in land use planning for the maintenance of a herbarium.

Qualifications and terms: A degree in Agriculture, Agricultural Botany or Natural Science and experience in ecological research. Salary £1,180 to £2,600 a year plus 25% gratuity. A supplement ranging from £200 to £300 a year is also payable direct to an officer's home bank account. Both the gratuity and supplement are normally tax-free. Contract 3 years.

**A contributory pension scheme is available in certain circumstances.**

(437)

*For further particulars of these vacancies and an application form please write giving your full name, age and brief details of professional qualifications and experience, and quoting appropriate reference number, to the Appointments Officer, Room 324. N/7*

**MINISTRY OF OVERSEAS DEVELOPMENT**

**Eland House, Stag Place, London SW1.**

**CSIRO**

## **AUSTRALIA RESEARCH SCIENTIST DIVISION OF WILDLIFE RESEARCH**

**GENERAL.** The Division of Wildlife Research has its headquarters at Canberra and a total staff of about 110, some of whom are located at other centres, including Perth and Alice Springs. Its officers carry out studies of wild mammals and birds ranging from basic research on animal ecology, animal behaviour, physiology of reproduction, parasitology, biochemistry and nutrition, to the assessment of the economic importance of wildlife species and the way in which biological knowledge may be applied in the management of wildlife resources. The appointee will be located in Canberra.

**DUTIES.** The appointee will be required to undertake a study of the epidemiology of myxomatosis, with a view to assessing the present status of the disease in various geographic regions in eastern Australia. Within this framework he will also have opportunity to develop aspects of his particular research interest.

The appointee will work in collaboration with a group of ecologists studying rabbit populations in geographic regions in eastern Australia representing semi-arid, sub-alpine, sub-tropical, coastal and temperate mediterranean habitats, and will maintain close contact with workers in the Division of Animal Genetics, CSIRO.

**QUALIFICATIONS.** Applicants should possess a Ph.D. degree in Science, or have had postgraduate research experience of an equivalent standard and duration, preferably in the field of ecology, supported by satisfactory evidence of research ability. Experience with animal ectoparasites or disease vectors would be an advantage.

**SALARY.** Depending upon qualifications and experience, the appointment will be made within the salary ranges of Research Scientist, \$A5,250–\$A6,622 p.a., or Senior Research Scientist, \$A6,892–\$A7,974 p.a. Salary rates for women are \$A428 p.a. less than the corresponding rates for men. Promotion within CSIRO to a higher classification is determined by merit.

**CONDITIONS.** The duration of the appointment will be determined in consultation with the successful candidate; some applicants may prefer a fixed term appointment for three years in which case consideration may be given to the continuation of F.S.S.U. arrangements.

Fares paid for the appointee and his dependent family. If the appointee is at present domiciled outside Australia, return fares will be paid at the conclusion of a fixed term appointment. Further particulars supplied on application to:

Mr. R. F. Turnbull, Chief Scientific Liaison Officer, Australian Scientific Liaison Office, Africa House, Kingsway, London, W.C.2, to whom applications (quoting Appointment No. 560/226) should be addressed by the **1st September, 1967.** (500)

## **FREELANCE TRANSLATORS**

Organon, Oss, Holland, manufacturers of ethical pharmaceuticals, require the services of freelance translators resident in the United Kingdom. Candidates should be able to translate Dutch, French, or German texts in the medical and pharmaceutical field into English. Remuneration will be in accordance with the usual freelance rates. Letters of application giving age, qualifications and experience should be addressed to

**TRANSLATION, C.A.D.,  
N. V. ORGANON, OSS, HOLLAND.**

(447)

## **UNIVERSITY OF EDINBURGH**

### **Technician**

required for Department of Machine Intelligence and Perception. The duties will include assisting with the design, construction and maintenance of experimental devices for use with the Department's Elliott 4100 computer, and maintenance of off-line electro-mechanical equipment.

Candidates should have had previous experience in assembling electronic equipment. The salary offered is in the range £683 to £968 per annum, according to age, qualifications and experience. Good working conditions and generous holidays.

Application forms may be obtained from The Secretary to the University, University of Edinburgh, Old College, South Bridge, Edinburgh 8. (453)

## **UNIVERSITY OF NEW SOUTH WALES**

### **LECTURER**

#### **SCHOOL OF CHEMICAL ENGINEERING**

Applications are invited for appointment to the above-mentioned position. Salary: \$A4,800 range \$A6,340 per annum. Commencing salary according to qualifications and experience. These salaries are under review. Applicants should hold a higher degree preferably in chemical engineering, mechanical engineering or metallurgy, and have had some experience in materials technology concerned with the specification, fabrication or corrosion aspects of industrial plant. The successful applicant will lecture to undergraduate students in the fields of materials and corrosion and will participate in the teaching of the postgraduate diploma in corrosion technology. Teaching experience is desirable but not essential.

Details of appointment, including superannuation, study leave and housing scheme, may be obtained from the Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1. Applications close in Australia and London on October 30, 1967. (468)

## **UNIVERSITY OF NOTTINGHAM**

### **CELL BIOLOGY UNIT**

#### **DEPARTMENTS OF BOTANY AND ZOOLOGY**

Senior Technician required to organize laboratories for both teaching and research purposes and to maintain apparatus for same. Previous experience in this type of work essential, some administrative experience desirable. Candidates should have A.I.S.T., H.N.C. in Applied Biology or equivalent. Salary within the range £992 to £1,230 per annum.

Storekeeper/Technician required to take charge of stores and apparatus in newly equipped unit and to assist the Senior Technician. Previous experience with chemicals and scientific apparatus would be advantageous. Salary within the range £653 to £1,018 per annum.

Junior Technician to assist in the organization of laboratories for both teaching and research. 37½ hour, 5-day week. Part-time day release for studies. Salary within the range £326 to £579 per annum.

Written applications only to the Registrar, giving details of age, experience and qualifications. (470)

## **INSTITUTE OF NEUROLOGY (UNIVERSITY OF LONDON)**

**GRADUATE RESEARCH ASSISTANT** required in the Department of Chemical Pathology to work on protein metabolism in brain by tracer techniques. The appointment will be for one year in the first instance but may be extended. The initial salary will be not less than £900 per annum.

Applications, giving a short curriculum vitae and the names of two referees, should be made in writing to The Secretary, Institute of Neurology, The National Hospital, Queen Square, London W.C.1. (428)

## pharmaceutical biochemist

A vacancy exists for a Biochemist having an interest in enzyme kinetics. The person appointed will join a team studying various aspects of the biochemistry of drugs and will be responsible for the enzymic and certain other specialised studies of the research programme.

Applications are invited from honour graduates in biochemistry who have about three years experience in pharmaceutical biochemistry.

The Company has a non-contributory Pension and Life Assurance Scheme, and a Profit Sharing Plan.

*Please apply, giving full details to:*

D. J. Goddard, Personnel Manager (R/G/7).

**NICHOLAS RESEARCH INSTITUTE LTD.**

225 Bath Road, Slough, Bucks.

A MEMBER OF THE ASPRO-NICHOLAS GROUP

(477)

## SCIENCE RESEARCH COUNCIL

## THE RUTHERFORD LABORATORY

## Scientific Administration

There is a vacancy for a **Principal Scientific Officer** to take charge of the Scientific Administration Group at the Rutherford Laboratory which is the leading research establishment in elementary particle physics in the United Kingdom.

This group, although numerically small, covers a wide range of work, including library and information services, university liaison, public relations, technical writing, documentation and the secretarial servicing of scientific and technical committees and conferences. In addition to supervising the Group, the successful applicant will be expected to make a personal contribution as a writer and interpreter of scientific work for non-specialists.

Applicants should have a good Honours degree, preferably in Physics or in Mathematics or Engineering, and be experienced in the administration of scientific work.

**Salary Scale: £2,410-£3,325 per annum**

There is a contributory superannuation scheme and housing may be available.

*Please send a postcard for application form to Mr. G. N. Pickles, The Rutherford Laboratory, Chilton, Didcot, Berks, quoting reference 409/34.*

Closing Date: 17th August, 1967.

(452)

## IMPERIAL COLLEGE

**ASSISTANT EXPERIMENTAL OFFICER** for field and laboratory work with pesticides and soil organisms at the Field Station. Candidates should possess a degree or equivalent in Horticulture, Agricultural Botany or a biological subject. Salary according to age and experience. Applications to: Dr. N. G. Hague, Imperial College Field Station, Ashurst Lodge, Sunninghill, Ascot, Berks. (480)

**SENIOR MICROBIOLOGIST/BIOLOGIST** required to take charge of Biological Department of Food and Drug Laboratory. Person appointed must be capable of dealing with a wide range of microbiological problems, the identification of insect parts, the microscopic identification of various constituents of foods and drugs (including pollen grains in honey) and the determination of antibiotics. Salary range £1,500 to £2,000 per annum.—Apply Thomas McLachlan, 4 Hanway Place, W.1. (475)

## PLANT BREEDING INSTITUTE CAMBRIDGE

### DEVELOPMENTAL GENETICS

It is proposed to appoint a Scientific Officer in the Cytogenetics Section to work on developmental aspects of the present programme for the cytogenetic analysis of wheat. Applicants should have good degrees and interest in the developmental physiology of plants and in genetics. The salary will be in the range £926 to £1,574 with superannuation under F.S.S.U.

Applications, with full personal particulars and naming three referees, should be sent to the Secretary, Plant Breeding Institute, Trumpington, Cambridge, by September 1. (494)

## NATIONAL INSTITUTE FOR RESEARCH IN DAIRYING (UNIVERSITY OF READING)

Applications are invited from persons with veterinary qualifications or suitably qualified research scientists to join a research team at the Institute where a study is being made of the control of mastitis in the dairy cow and where large-scale field trials are being carried out in co-operation with the Central Veterinary Laboratory of the Ministry of Agriculture. The person appointed will be required to take part in investigations where particular emphasis will be given to the development and testing of skin disinfectants and the cause and prevention of skin blemishes. The appointment will be for a period of three years and it may be possible for the successful applicant to be registered in the University of Reading for a higher degree. The salary will be within the scale for Scientific Officers (£926 to £1,574) according to age and experience.

Apply, naming two referees, to the Secretary, N.I.R.D., Shinfield, Reading, Berks. Please quote ref. 67/26. (440)

## GREAT OUSE RIVER AUTHORITY APPOINTMENT OF ASSISTANT CHEMIST (BIOLOGIST/MICROBIOLOGIST)

Applications are invited for the above appointment in the Pollution Prevention Laboratory of the Authority. Applicants should have an appropriate degree, H.N.C. in Applied Biology or equivalent and preference will be given to those with experience of fresh water ecology and microbiology, and fish diseases. The successful applicant will be expected to help in the chemical laboratory when necessary. Salary will be within the scales AP-2-3 (£1,020 to £1,435), the starting point to be dependent upon qualifications and experience. The National Joint Council conditions of service apply to the post which is superannuable and subject to medical examination. A five-day week is worked. Half cost of reasonable removal expenses will be paid in approved cases.

Applications should be made to The Clerk to the Authority, Great Ouse House, Clarendon Road, Cambridge, by August 21, 1967.

J. S. BISSETT,  
Clerk to the Authority.  
(492)

## THE UNIVERSITY OF MANCHESTER MANCHESTER, 13

### RADIATION OFFICER IN THE

### DEPARTMENT OF PHYSICS

Applications invited from graduates for this post. Knowledge of radiation protection and electronics additional qualifications though not essential. Salary range per annum: either £920 to £1,525; or £1,450 to £2,200, according to qualifications and experience. F.S.S.U.

Particulars and application forms (returnable by August 26), from the Registrar. Quote ref. 120/67/Na. (441)

## THE UNIVERSITY OF MANCHESTER MANCHESTER, 13

### LECTURER IN PHYSICS

Applications invited for above post. The successful candidate will be expected to pursue research in Experimental High Energy Physics. The High Energy group is engaged in experiments using wire spark chambers, counters and on-line computers at the 5 GeV electron synchrotron at Daresbury, Nr. Warrington. Salary range £1,470 to £2,630 per annum. F.S.S.U.

Particulars and application forms (returnable by August 31) from the Registrar. Quote Ref. 119/67/Na. (442)

## ESTABLISHMENT OF PHYSICS GROUP

BCIRA conducts experimental research and development on all aspects of the production, performance in service, metallurgy and inspection of iron castings. The establishment of a **Physics Group** is planned. A physicist is already established as a leader of the group, and BCIRA now has vacancies for physicists to assist in the development of the effort.

The work of the group will cover many topics and will immediately involve responsibility for work with an electron probe micro-analyser, a fundamental project on the electrical and magnetic properties of liquid iron alloys with a view to producing new control techniques, and the development of non-destructive techniques for the determination of structure and properties.

The group will be expected to initiate its own programme of fundamental and applied work which should involve laboratory and industrial experience. The posts provide opportunity for experience in a wide field, and considerable scope, especially for young men with good honours degrees in pure or applied physics, but also for corporate members of the Institute of Physics and for those with HNC.

The laboratories are situated in pleasant rural surroundings within easy reach of Birmingham, Redditch and Coventry. Good opportunities are provided for travel and for publication of results, as well as for maintaining contact with relevant fields of knowledge, both academic and industrial.

Starting salaries will be in the range £1,150–£2,000 per annum, depending on age, experience and qualifications. Staff application forms can be obtained from:

**DIRECTOR,  
British Cast Iron Research Association**  
Alvechurch, Birmingham.

(438)

## microbiologist

A young microbiologist is required in the quality control section of our Microbiological Laboratory. In addition to quality control work, the position will involve working on development projects.

The successful applicant will have a minimum qualification of ONC in biological subjects. Some experience in biological control testing is desirable.

The starting salary will be in the range £750–£950 dependent on age, qualifications and experience.

The Company has a non-contributory Pension and Life Assurance Scheme, and a Profit Sharing Plan.

*Please write, giving full details, to :*

D. J. Goddard, Personnel Manager (R/G/8),

**NICHOLAS RESEARCH INSTITUTE LTD.**

225 Bath Road, Slough, Bucks.

A MEMBER OF THE ASPRO-NICHOLAS GROUP.

(476)

### UNIVERSITY OF EDINBURGH

## Senior Systems Programmer

required to write a LISP 1.5 Interpreter and Compiler for the System 4/75 English Electric multi-access system which is to be installed in the Edinburgh Regional Computer Centre next year. The appointment will be for one year, in the first place, but there should be opportunities for re-appointment in the university or the Regional Centre thereafter. Salary will be from £1,800 upwards, depending on qualifications of candidate. The appointment will be made as soon as there is a suitable candidate.

There is also a possible opening for a junior appointment of a graduate assistant in programming.

Applications, by letter, should be sent to Dr. B. Meltzer, Metamathematics Unit, 5 Buccleuch Place, Edinburgh, 8. (444)

### MINISTRY OF OVERSEAS DEVELOPMENT

The Tropical Pesticides Research Headquarters and Information Unit of the Ministry requires a Scientific Assistant to deal with the maintenance of snail cultures, testing of chemicals as possible molluscicides for the control of Bilharzia and to assist in experiments to investigate the mode of action of these chemicals.

Applicants must have at least four "O" level passes, including English language and a scientific or mathematical subject, together with at least one year's practical experience. Salary according to age in the scale £456 to £1,055 (including Inner London weighting).

Applications to the Director, Tropical Pesticides Research Headquarters and Information Unit, Tropical Products Institute, 56-62 Gray's Inn Road, London, W.C.1, before August 14, 1967. (435)

### UNIVERSITY OF LIVERPOOL

#### PHYSICAL CHEMIST OR BIOPHYSICIST

Applications are invited for the post of Research Fellow or Research Assistant, according to the qualifications of the successful applicant in the Immunology Cancer Research Unit. Postgraduate research experience and/or higher degree desirable, but not essential. Opportunities for both personal research and team-work in excellently equipped new laboratories. Initial salary within the range £1,200 to £2,000 per annum (plus F.S.S.U.), according to qualifications and experience.

Applications, naming three referees, to the Registrar, The University, Liverpool 3. Please quote Ref.: RV/99/N. (404)

### UNIVERSITY OF DUNDEE

#### COX CHAIR OF ANATOMY

Applications are invited for the Cox Chair of Anatomy which falls vacant from January 1, 1968 on the appointment of Professor R. E. Coupland to the Chair of Human Morphology at the University of Nottingham. Salary £4,620. F.S.S.U.; grant towards removal of household effects.

Applications (fifteen copies—overseas applicants one copy), containing the names of three referees to be lodged not later than August 26, 1967, with the Secretary, The University, Dundee, from whom further particulars may be obtained. (439)

# PLANT BREEDING INSTITUTE CAMBRIDGE

**ENTOMOLOGIST** required for a new post to study resistance to aphids in sugar beet and other crop plants. Appointment at Scientific Officer level within the salary scale £926 to £1,574, according to age and experience. First or Upper-Second Class Honours degree essential and post-graduate experience in entomology would be an advantage. Superannuation under F.S.S.U.

Applications, giving full personal particulars and naming three referees, to The Secretary, Plant Breeding Institute, Maris Lane, Trumpington, Cambridge, by September 1. (495)

# COLLEGE OF MEDICINE OF THE UNIVERSITY OF LAGOS

Applications are invited for the following appointments in the newly-created Department of Radiation Biology and Radiotherapy:

(a) Lectureship Grade I in Radiotherapy. Candidates must be medically qualified with D.M.R.T., F.F.R., or equivalent.

(b) Lectureship Grade I or II in Medical Physics or Biophysics. Candidates must possess Ph.D. in Medical Physics.

Appointees will be considered for appointment to honorary consultancies to Lagos University Teaching Hospital. Salary scales: Grade I £2,200 to £2,600 per annum; Grade II, £1,200 to £2,100 per annum. 20 per cent supplementation basic salary (generally free of income tax) payable to U.K. staff. Family passages; children's and car allowances; superannuation scheme; regular U.K. leave.

Detailed applications (six copies), naming three referees, as soon as possible to Inter-University Council, 33 Bedford Place, London, W.C.1, from whom particulars are available. (449)

# UNIVERSITY OF MANCHESTER

Applications are invited for the post of Senior Technician in the Department of Bacteriology and Virology. Applicants should have had previous bacteriological experience and may work either in the preparation of class material or be in charge of the central services unit. Salary in accordance with the University's Scales for Senior Technicians (£942 to £1,180 per annum). Registered technicians may be considered for National Health Service rates of pay (£994 to £1,727).

Applications, with full details of age, experience and names of two referees, should be sent to the Secretary, Dept. of Bacteriology and Virology, Williamson Building, Brunswick Street, Manchester 13. (481)

# UNIVERSITY OF MANCHESTER MANCHESTER, 13

# EXPERIMENTAL OFFICER OR SENIOR EXPERIMENTAL OFFICER IN METALLURGY

Applications invited for this post for work in electronics, on research projects in Department of Metallurgy in Faculty of Science. Expansion requires automation of testing equipment or development and construction of new apparatus for specific measurements. Knowledge and experience of wide range of electronic techniques and devices required. Officer should, under own initiative, be able to consider measurement problems in terms of electronic devices and know how to develop, construct or purchase suitable instruments. Suitable qualifications: Degree, Dip.Tech., or H.N.C. Other qualifications considered if experience relevant. Salary ranges per annum. E.O. £920 to £1,525; S.E.O. £1,450 to £2,200. F.S.S.U.

Particulars and application forms (returnable by August 31), from the Registrar, the University, Manchester 13. Quote Ref. 124/67/Na. (482)

**EAST MALLING RESEARCH STATION.** Vacancies for graduates in Statistics or Mathematics. Research encouraged. Biological or horticultural interests an asset. Access to computers. Appointment in the Scientific Officer grade.—Further details and application forms from the Secretary, East Malling Research Station, Maidstone, Kent. (436)

# Scientific Civil Service

# FORESTRY COMMISSION

**ASSISTANT GENETICIST** (graded S.S.O.) required to fill post at the proposed Forestry Research Station to be built near Edinburgh to carry out research work concerned with problems of flowering and fruiting of forest trees, vegetative propagation problems connected with forest trees, growth analysis and early progeny test procedures. Would take charge of small laboratory, glass houses and growth room facilities. Services of two Scientific Assistants and four foresters available. Candidates should be between the ages of 27 and 35 years and should have a good honours degree in an appropriate subject with post-graduate training in genetics, biochemistry or plant physiology.

**QUALIFICATIONS:** 1st or 2nd class honours degree, or equivalent or higher qualification in appropriate subject and at least 3 years' post-graduate experience in genetics, biochemistry or plant physiology.

**SALARY** (minimum age 26): £1,744 to £2,155.

Non-contributory pension, promotion prospects.

**APPLICATION FORMS** from Civil Service Commission, Savile Row, London, W.1, quoting S/53/FC. Closing date August 29, 1967. (451)

# GOVERNMENT OF NORTHERN IRELAND SENIOR SCIENTIFIC OFFICER/SCIENTIFIC OFFICER

Applications are invited for a pensionable post in the Agricultural Bacteriology Division of the Ministry of Agriculture.

# QUALIFICATIONS:

Honours Degree in Agriculture, Science or Food Science preferably with post-graduate experience in Bacteriology.

# DUTIES:

The successful candidate will be expected to undertake research and investigational work in connection mainly with the bacteriology of meat and meat products and may be required to undertake teaching duties in the Faculty of Agriculture, Queen's University, Belfast. Facilities are available for registration for a higher degree.

# SALARY SCALES:

Senior Scientific Officer £1,744 to £2,155

Scientific Officer £926 to £1,574

Grading and starting salary will depend on qualifications and experience. There are prospects of progression to Principal Scientific Officer.

Application forms, obtainable from the Secretary, Civil Service Commission, Stormont, Belfast, 4, must be returned by August 18, 1967. Please quote SB92/67/64. (454)

# THE ARTHUR D. LITTLE RESEARCH INSTITUTE

wishes to recruit a

# Physical Chemist

to join a group concerned with long-range research into the study of new materials. Research experience in the field of polymer characterization, optical studies or electrical behaviour would be an advantage, but is not essential. The Institute is concerned generally with a variety of long-range projects in the fields of physics, chemistry and biology, and is situated in pleasant rural surroundings within 6 miles from the centre of Edinburgh.

Applications, giving particulars of qualifications and experience should be sent to: The Personnel Officer, Arthur D. Little Research Institute, Inveresk Gate, Musselburgh, MIDLOTHIAN. (469)

## Patent/Licensing Officers

A major Company in the plastics and chemical industries employing 11,000 people, wishes to appoint two Patent/Licensing Officers to work in the Patents Department at Tyseley, near Birmingham. General terms and conditions of employment are good, as are the career prospects for the men appointed.

The successful candidates will undertake general patents work in the fields of plastics manufacture and fabrication with particular emphasis on either:

- a) preparation and filing of British and overseas patent applications
- or b) Licensing of patents and technology.

Applicants should have a good honours degree in chemistry, chemical engineering or engineering and at least 3 years experience in patents and/or licensing work.

**Please write, giving brief details of qualifications and experience to:**

**The Staff Manager, Bakelite Xylonite Ltd.  
Enford House, 139-151 Marylebone Road,  
London, NW1**

(478)

## NEW ZEALAND

University of Canterbury  
Christchurch

### READER IN MATHEMATICS

Applications are invited for the above-mentioned position. Qualifications in either pure or applied mathematics will be acceptable but applicants having interests in the fields of numerical mathematics or statistics would be particularly welcome. The Department is equipped with an I.B.M. 1620 computer, and an I.B.M. 360/44 computer will be installed in August, 1967. The salary will be between \$NZ5,600 and \$NZ6,600 per annum, commencing salary being in accordance with qualifications and experience. (\$NZ2=£1.) Approved fares to Christchurch will be allowed for the appointee and his dependent family, together with actual removal expenses within specified limits.

Further particulars and information as to the method of application may be obtained from the Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1. Applications close on September 30, 1967. (484)

### BUREAU OF SUGAR EXPERIMENT STATIONS

QUEENSLAND, AUSTRALIA

Applications are invited for appointment to the position of Assistant Director. The appointee will be required to take up duty at the Bureau's Head Office in Brisbane on July 1, 1968.

The Bureau of Sugar Experiment Stations is the official research organization of the Queensland sugar industry, and is administered by the Sugar Experiment Stations Board; it is a semi-Government instrumentality.

Applicants should be graduates of an approved university, and should submit with their applications evidence of scientific and administrative ability. The position to be filled is a technical-administrative one and the appointee would be required to assist in administering the activities of the organization in the fields of agronomy, entomology, cane breeding, pathology, extension and sugar-mill technology. His training and experience should be in the agricultural field.

The salary applicable to the position is within the range of \$A8,626 to \$A9,026 per annum (£1 Sterling is equivalent to \$A2.50). The appointee would be required to join the Bureau's Superannuation Scheme after three months' service. Housing or quarters are not supplied.

Previous experience in the cane-sugar industry is not essential, but preference would be given to applicants with a wide experience in a research phase of sugar-cane agriculture.

Applications, supported by complete details of academic training, experience and published work should be addressed to the Director, Bureau of Sugar Experiment Stations, 99 Gregory Terrace, Brisbane, Australia, so as to arrive by November 15, 1967. Applications may be endorsed on the envelope "Confidential—Application for Position." (459)

### UNIVERSITY OF SHEFFIELD DEPARTMENT OF PHYSIOLOGY

Applications are invited for a post of LECTURER or ASSISTANT LECTURER in PHYSIOLOGY duties to begin as soon as possible. The Assistant Lectureship would be suitable for a candidate wishing to study for primary F.R.C.S. Initial salary according to qualifications and experience in the ranges: for candidates holding a registered medical qualification: Lecturer, £2,005 to £2,755; Assistant Lecturer, £1,470 to £1,830; for other candidates: Lecturer, £1,470 to £2,630; Assistant Lecturer, £1,105 to £1,340 with F.S.S.U. provision.

Further particulars from the Registrar, to whom applications (six copies), should be sent by September 2, 1967. (487)

THE LONDON HOSPITAL, WHITE-chapel, E.1. GRADUATE PHYSIOLOGIST required for research project in this large Teaching Hospital. For a suitable candidate, facilities may be available to obtain either a M.Sc. or M.Phil. degree. Salary according to age, experience and degree.—Written applications, naming two referees, to the House Governor by August 19, 1967. (455)

### SIR JOHN CASS COLLEGE

#### Department of Chemistry

Applications are invited for the post of LECTURER or ASSISTANT LECTURER with special interest in OPTICAL SPECTROSCOPY, to commence in either October 1967 or January 1968.

Applicants should be qualified to lecture in Inorganic or Physical Chemistry to honours degree standard, and must have active research interests in Spectroscopy.

Salaries are within the following scales: Assistant Lecturer (Grade B): £1,175 to £1,845; Lecturer: £1,875 to £2,140; plus, in each case, London Allowance of £70.

Application forms and further particulars may be obtained from the Secretary, Sir John Cass College, Jewry Street, London, E.C.3. The closing date for applications is August 21, 1967. (456)

### UNIVERSITY OF LIVERPOOL

#### IMMUNOLOGY CANCER RESEARCH UNIT

SENIOR TECHNICIAN required for the Research Laboratory with either Associate-ship or Fellowship of the I.M.L.T. Experience in the handling of staff is desirable with a practical understanding of the problems of routine supply and administration of a research laboratory. Familiarity with histological, immunofluorescent, or radio-isotope techniques an advantage, but not essential. Excellently equipped new laboratories.

Salary on the scale £994 to £1,303 per annum according to qualifications and experience.

Application forms may be obtained from the Registrar, The University, Liverpool 3. Please quote Ref. RV/96/N. (402)

### PLANT BREEDING INSTITUTE CAMBRIDGE

#### CEREAL CYTOGENETICS

It is proposed to appoint a Scientific Officer to work on applied and fundamental aspects of the chromosomal organisation of barley. This work will be associated with that of the Cytogenetics and the Cereal Breeding Sections of the Institute. Applicants should have good degrees in Genetics or Botany. The salary will be in the range £926 to £1,574 with superannuation under F.S.S.U.

Applications, with full personal particulars and naming three referees, should be sent to the Secretary, Plant Breeding Institute, Cambridge, by September 1. (493)

### BIRMINGHAM (DUDLEY ROAD) GROUP OF HOSPITALS

Biometric or Cardio Respiratory Function Technician required for Respiratory Function Laboratory and Cardiological Department at Dudley Road Hospital. The person appointed should have had previous experience in the field and be suitably qualified. Salary scale £1,333 rising to £1,727 per annum.

Applications in writing naming two referees, to Group Secretary, Dudley Road Hospital, Birmingham 18, by August 19, 1967. (457)

## PROBLEMS OF SCALE

THE publication of the report on the Aberfan disaster, when a coaltip slipped down the side of a Welsh valley last year and killed 145 people, most of them children, has been a dramatic business (HMSO, 15s.). For one thing, the occasion has released a great flood of comment, criticism and emotion which was necessarily pent up while the judicial tribunal was in session. But the report has also been unexpectedly forthright in its criticism of the National Coal Board and surprisingly frank in singling out for blame individual officials of the board. The tribunal's conclusion, from which nobody has yet dissented, is briefly that the disaster could and should have been prevented. It only happened because of "ignorance, ineptitude and a failure of communications" within the board. Lord Robens, the chairman of the coal board, comes in for deliberate criticism, partly because of a hasty but ill-considered attempt to claim that the disaster could not have been foreseen, but more seriously because the coal board did not willingly admit its responsibility to the tribunal.

In reality the circumstances which led to the disaster were neither unusual nor unforeseeable. Indeed the particular coaltip which eventually engulfed the school at Aberfan had slipped some hundreds of feet down the mountainside in 1963. A companion coaltip had slipped almost as far as the village in 1944. For several years the villagers had complained to the coal board of what seemed to them a serious and an imminent danger. In the circumstances it is only natural that Lord Robens should have chosen to offer his resignation. (This remains in abeyance until the end of August, when the coal board is due to make its own proposals for reform to the Minister of Power.) It is also natural that everybody should now be determined that coaltips should never slide again, and this objective will probably be easily attainable. It is, however, much less easy to be sure that other problems made obvious by the Aberfan disaster, and which are in many ways bound up with the growth of industries of all kinds, will be as closely attended to, or even as fully appreciated.

The growing scale on which modern industry—and even the modern coal industry—must function is one aspect of the Aberfan disaster which tends to be forgotten. Last October there were close on three million cubic yards of colliery waste on the hillsides above Aberfan. For more than half a century until the newest of the seven spoil heaps slid down the mountainside,

tipping had continued at a rate which works out at an average of 57,000 cubic yards a year. This rubble was being heaped on to a hillside falling uniformly into the valley beneath at a gradient of one in five. As it happens, the complex of coal tips intersected a geological fault (plainly to be seen on the appropriate maps) and the natural springs associated with it, to say nothing of a number of natural water courses. It seems to be agreed that the disaster happened because water accumulated within the seventh coaltip to such an extent that hydrostatic pressure was able to set in train a bodily movement of one part of the tip. When that had begun, it is no surprise at all that the downward movement of the mass of rubble should have carried for 2,000 feet downhill and that it should in the process have carried away several houses and most of the school. It is now clear that the moving mass scoured the thin layer of boulder clay from the sides of the glacial valley and thus released water stored in the natural aquifers of the underlying sandstone, which then discharged itself catastrophically as a flood on the village underneath.

Plainly the scale of this phenomenon was almost geological and this, no doubt, is part of the reason why the officials of the National Coal Board now held to have been responsible for the neglect of safety should have failed to appreciate the danger of tipping on such a water-sodden hillside. They would have been used, in their daily work, to seeing truckloads of coal, five or ten tons at a time, piled neatly into stable heaps. There would have been little in their everyday experience to suggest that a heap of waste one hundred thousand times as big might behave in quite a different fashion. There is plenty of evidence in the report of the tribunal to show how whimsical were some of the attempts at foreseeing what might happen. One colliery official, for example, who stands out as being alone prepared to consider the possibility that waste might actually reach the village from the coaltips, seems to have thought that even in this unlikely event—to him—there would be plenty of time in which people could be warned to evacuate their houses. The larger the mass, the slower the acceleration—that seems to have been this unfortunate man's intuitive notion of acceleration down an inclined plane. But for most of those concerned with the tips, large scale movement seems to have been quite beyond the bounds of possibility. The tribunal in its report points out that those in charge of coaltips would have appreciated

the danger at Aberfan more readily if they had thought of how sandcastles on the beach can be brought down by a little water, but this point would have occurred only to people anxiously seeking criteria to decide when coaltips would be safe. So indifferent to the possibility of catastrophe were the engineers in charge of these operations that they were not even alerted by the circulation in 1965 of a memorandum spelling out procedures for tipping colliery waste that would have ruled tips at Aberfan completely out of court. (The memorandum was itself, ironically, derived from what the coal industry is inclined to think of as the bad old days before nationalization.) The tribunal is right to describe this state of affairs as akin to blindness. Without excusing in any way the slackness in the coal board, it is entirely fair to say that the failure of the several officials was a failure to appreciate the scale on which they were operating.

From this it follows that in the search now being made for other potential disasters, coaltips are only some of the artefacts which should be thought of. By now there is plenty of experience to show that gigantic catastrophes can follow large scale reservoir construction, for example. Here too, unfortunately, bitter experience has been more formative than foresight. It took the disaster at Fréjus nearly ten years ago to emphasize the importance of rooting concrete dams in sound rock. Other fatalities have been necessary to show that water in a dammed up lake, like water in a bathtub, can slosh about from one end to another with serious consequences. Huge coastal works can create problems as well as solving them. There seems to be a growing suspicion that tall buildings can form patterns of air movement which cannot easily be anticipated from experience with much smaller structures—the failure of the electricity cooling towers of the Central Electricity Generating Board at Ferrybridge two years ago is yet another sign that scaling up is necessarily difficult. And what will happen when cities become even larger than they are now, so that their output of heat and chemicals to the environment is even greater than at present? Fortunately it is usually possible to work out the probable consequences of gigantic scale. In most fields engineers are now ready to acknowledge that there is no substitute for model experiments intended to throw light on unfamiliar circumstances. To say all this is not to imply that scaling up should be avoided—indeed, it is essential that things should get bigger as time goes on. One of the immediate consequences of the Aberfan disaster should be to make all kinds of engineers more sensitive to the need to anticipate what problems there may be. It is the peculiar fault of the coal industry that it was able smugly to ignore all the risks it ran.

And why so blind? One of the most bitter ironies in the report of the tribunal is that most of the men singled out for blame appear to have been not merely conscientious but even vigorous about almost everything but the management of coaltips. Most of the men concerned were what is called self-made men. Some of them, for example, had gone into coalmining

at fifteen and had been able to work their way to positions of responsibility by hard work and devotion. In one sense it is cruel that their reputations should now be ruined on account of a failure which their training had not equipped them to appreciate. But the same people were led by their long experience to believe that they knew everything there is to know about coalmining—which is why they chose to fob off complaining villagers with fairy stories intended to suggest that they had made a sober appraisal of the situation. It is hard to believe that so many people would have been so complacent if they had had wider experience outside coalmining. In the circumstances it is essential that in the programme of reform on which the coal board must now embark, it should take vigorous steps to see that people with positions of responsibility in the industry are given the kind of further education and training necessary to see that they can do their jobs effectively. To say this is not to suggest that people should not be allowed to work their way up from the bottom, but, on the contrary, that job training is as important for individuals moving up the industrial hierarchy as instruction in arithmetic is for children at school. This is as true for other industries in Britain as it is for coalmining. The coal board should be spurred on by the recognition that the disaster at Aberfan may only be the most spectacular of the deficiencies of its organization which can be blamed on insufficient attention to vocational training.

As it happens, the people trained in engineering seem to have been as indifferent to the dangers at Aberfan as were the self-made men, which only goes to show that formal training is not enough to allow people to operate efficiently in modern industry. The professionals, however, were prevented from contributing efficiently to the prevention of disaster by the absurd way in which old-fashioned caste systems have been imported into the mining industry. The distinction between civil and mechanical engineers seems to have been as clear at Aberfan as it was when Stephenson created the Institution of Mechanical Engineers as a slap in the face for the stuffer civil engineers. (One curious anomaly in mining is that mechanical and not civil engineers are formally responsible for such tipping policies as there are.) From the report of the tribunal it emerges clearly that there will now be a movement to make sure that people in pits are given some formal training in soil mechanics, which will do no harm and possibly some good. But in the long run it is more important that professional people employed in mining, and in other industries for that matter, should be trained for flexibility. It is just possible that the real interests of the coal industry will not be served if there is now a concentrated attempt to make the education of mining engineers still more specialized, so that they are able to do everything they do at present and to manage coaltips as well. It could easily be much more valuable if engineers with experience right outside the industry were tempted into positions where their wider experience could serve not merely to prevent accidents but to introduce new ideas as well.

## NEWS AND VIEWS

### Selling Space

THE House of Commons Estimates Committee has just completed the exhausting task of surveying the British space research effort. The results are described in a highly critical report, published this week (HMSO, £1 18s.). "On the whole it has been a story of wasted opportunities brought about by lack of purpose and the lack of any coherent organization. There has been no real space policy and no space programme as such."

The report deals with each of the international organizations in turn. Although ELDO has so far cost Britain £49.8 million, only one buyer (France) is in view for the ELDO PAS launcher which the project is intended to develop. In ESRO, Britain has spent £11 million, and obtained contracts worth £4 million in exchange. France, the committee bitterly points out, has obtained contracts worth more than double what she has so far contributed. On the scientific side, the committee is no happier; ESRO 11 should have been launched by NASA—free of charge—early in 1967, but the Scout launcher failed. It will now be launched in late 1967 or early 1968, about the same time as ESRO 1. As for the large astronomical satellite (LAS) which was to be launched in 1970 as the climax to the ESRO programme, the committee believes that it will be 1972 or 1973 before it is in orbit. CETS, the committee says, is not an organization but a "continuing conference". "Its continued existence in its present form," the committee declares, "would appear unlikely to achieve any useful purpose." In Britain, the decision to proceed with the Black Arrow programme was the right one, but was taken too late: "the fact that in the end the right decision was reached in no way condones the delay in arriving at it".

As the committee discovered, there is no such thing as a British space programme; expenditures and projects are considered on a piecemeal basis. The committee recommends that a space programme with a budget of its own should be drawn up and agreed for the next five years. The Minister of Technology should take charge of the programme, and appoint a minister of state with responsibilities solely for space. The committee believes the present level of expenditure, about £30 million a year, to be about the right figure. As a proportion of GNP it is rather larger than Germany or Japan, rather smaller than that of Italy or France. A much larger part of this money should be spent within Britain, however, and the correct ratio should be something like two to one in favour of national programmes. This, it admits, will be difficult to achieve within the budget suggested if the large contribution to ELDO (£9.7 million this year) is to continue. This is another reason, the committee feels, for questioning the future of ELDO; if it is to continue, the British contribution should not be allowed to rise. Similarly, Britain should oppose any attempt to increase the number of ELDO PAS launches. It should not

take part in the CETS programme for a television distribution satellite, but should attempt to produce a British military communications satellite to replace the existing Skynet satellites in 1971. Expenditure on the Black Arrow programme should be doubled from £3 million to £6 million, with the intention of using electrical propulsion to launch a small communications satellite.

Not all these suggestions will find favour with the Government. They are too closely identified with the space industry lobby and Conservative Party policy for that. In any case, the Government is unwilling to do anything which can be interpreted as anti-European. It is clear, though, that British space expenditures will not be allowed to rumble on untouched for much longer; within the next few months decisions must be taken to bring things under control.

### Non-treaty

HOPES for a nuclear non-proliferation treaty, so high three months ago, now seem to have sunk almost out of sight. Mr Fred Mulley, the British minister at Geneva, had some strong words to say on the subject last week. "I am extremely disappointed," he said, "to find on August 3 that we have no draft treaty before us and, as far as I can discover, have made no further progress towards achieving a non-proliferation treaty." He went on to say that if a draft is not tabled very soon, there may not be time to turn it into a treaty, and he urged the co-chairmen, particularly the USSR delegate, to get negotiations moving again.

The sticking point for the treaty is still the safeguards arrangements. Euratom countries have insisted that they be allowed to preserve the safeguards worked out within Euratom, while other countries have favoured safeguard arrangements in the hands of the IAEA. This impasse led to the suggestion that the treaty be drafted with the section on safeguards left blank, a proposal the USSR has so far refused to accept. It is clear that even if a draft acceptable to all the parties can be put together, there will be plenty of steam left in the arguments, and the transition from draft to treaty could be a long business.

The desire for a treaty has been given urgency by the very rapid advance of the Chinese to thermonuclear status. Neither China nor France, however, is represented at Geneva, which means that whatever treaty is signed France will not be a party to it. It is distasteful to other Euratom countries to reflect that if they sign the treaty they will be subject to inspections from which France is exempt; this is fundamentally opposed to the philosophy of share and share alike on which Euratom was once based. Of the other states near the threshold of nuclear status, Israel and Japan are not represented, but the UAR and India are. France is entitled to a seat at the negotiating table, but has not taken it up, and will presumably not sign the treaty.

The frustration at Geneva has tended to shift the spotlight to another problem under discussion there—the Comprehensive Test Ban Treaty. This too is making very slow progress, both for technical and political reasons. It is at present impossible to detect all underground nuclear explosions unambiguously by

long range seismic recording alone. The present detection threshold is about magnitude four, and 80–85 per cent of the earthquakes above this magnitude are identifiable. A recent Swedish memorandum to the committee has suggested that by processing the data in a certain way, and by the use of decision theory, the data now available are sufficient to provide at least a degree of deterrence to countries contemplating underground nuclear explosions. It is clear, though, that it is still not possible to distinguish with absolute certainty between explosions and earthquakes without on-site inspections. As Mr Mulley put it, "It may be that with further technological progress scientific techniques alone may provide the answer, even without on-site inspections . . . but my government does not believe that this point has yet been reached". Meanwhile the test ban treaty shares with the non-dissemination treaty the problem of inspection—and, of course, the depressing thought that neither France nor China has any intention of signing it.

## Ten Years Old

It is difficult to look back with much enthusiasm on the ten years in which the International Atomic Energy Agency has been in existence. The acquisition of nuclear weapons by China and France, and the adoption of idiosyncratic foreign policies by these two states, represents just the kind of situation that the IAEA was set up to prevent. Indeed, so limited were the powers accorded to the new organization at its inception that its failure was predictable even then. The agency may inspect nuclear installations only at the invitation of governments, and its fiercest sanction is to report misdemeanours to the General Assembly of the United Nations. At present, more than sixty plants in twenty-six countries are under its observation, but none of these is in France, West Germany, the Soviet Union, or, of course, China. Of the technologically advanced countries, only Japan, inspired by memories as well as reason, has co-operated whole-heartedly with the IAEA. Until more of its member states follow this example, the agency can only continue to gain experience of inspecting installations. This month one of its teams is investigating a newly built fuel reprocessing plant for the Yankee reactor at West Valley, New York. This is the first time that a plant other than a reactor has been inspected.

The IAEA has been more successful where its activities have not impinged on politics. More than two thousand five hundred fellowships have been awarded, and a large number of training courses arranged. Research is being undertaken into desalination, pest control by irradiation, the use of isotopes in medicine and hydrology, and other projects. Yet the budget of the agency is minute compared with that of national atomic energy authorities. In 1967, of a total of twelve million dollars, only three-quarters of a million were spent on research projects. The amount will rise by a mere fifty thousand dollars next year, according to the recently published budget for 1968. Even among the United Nations agencies, the IAEA is something of a Cinderella; WHO operates on a budget of nearly sixty million dollars.

Had the research work of the agency been more extensive, its control over the activity of member states

might have been greater, for its statutes stipulate that all of the agency's aid projects shall be open to inspection. As it is, with the bulk of nuclear research being done in regions far from Vienna, international projects have been set up independently of the IAEA, and only occasionally has the agency been invited to join the agreement, as a superfluous matchmaker. With the authority of scientific achievement, the IAEA might speak with a different voice, and be heard.

## Organizing Steel

DETAILS of the organization of the British Steel Corporation were recently completed, and have been published as a White Paper (HMSO, 4s.). The corporation came into existence on July 28, when fourteen British steel companies were nationalized. The BSC will have a total turnover of more than £1,000 million, and will employ 270,000 people; this, the White Paper notes, will put it among the six largest undertakings in the free world—outside the United States.

The organization takes into account two opposing forces, geography and product. Geographical groupings help in the physical problems of management and communications, but destroy valuable product links between companies. Grouping on product lines makes management, sales and research easier to co-ordinate, but reduces freedom of choice for the consumer and makes competition between the groups harder to sustain. In the event a compromise between these forces has been struck, and four regional groups are named in the White Paper. The Midland Group, centred in Sheffield, will do much of the stainless and special steel production; the Northern Group will look after tube, the Scottish and Northern Group strip milling and coated sheets, and the South Wales Group will account for the whole UK production of transformer sheet and tinplate. It is clear, though, that the groups will not be limited to these products, and a generous amount of overlapping on the more common steel products is likely.

The report says little about research and development in the corporation. Dr H. M. Finnieston, as deputy chairman-technical, will have two directors reporting to him, one on engineering, and the other on research and development. The director of engineering will look after the exploitation of research and development work, advise the groups on the engineering aspects of major capital projects, and distribute technical information. The director for research and development will be concerned with all the central research activities, technical processes, product development and measures designed to improve working conditions. The White Paper makes a point of mentioning that he will use techniques such as operational research. The names of the directors have not yet been announced.

The philosophy of the White Paper seems to be to develop a less monolithic structure than is customary in British nationalized industries. "Within the concept of a single, unified corporation, we consider that the Groups should have the greatest degree of operating autonomy and profit accountability. The spur of competition, other than in price, between the groups and the units below them is in our view highly desirable." Price competition, though, says the White Paper, is both unattainable and undesirable within a

single organization. It then goes on to demolish claims which British steel makers have been making in their battle against nationalization: "... true price competition has never operated successfully in this or any other country". It must have come as a great relief to some members of the board to be able, at last, to admit it.

## How to import Chemicals

RESEARCH workers, both in industry and universities, have been complaining about the difficulty of importing small chemical samples into this country. The samples are of compounds which are not manufactured here, and may be available only from a single firm abroad. Although they are given completely free by the manufacturers, and are clearly marked "For Scientific Purposes Only", they have, in certain cases, been subject to import duty. Even more annoying, delays in delivery are frequent; a box of samples that crosses the Atlantic in eight hours may take three weeks to reach the laboratory from London Airport.

The best way to be certain of the swift arrival of a shipment is to employ one of the freight agencies that handle goods at docks and airports. A laboratory will have to pay such an agent three or four pounds to have a case of samples sent through the customs, and put on the train. This sum may well be ten times the value of the chemicals, so that the privilege of receiving free gifts from American and European companies may cost a research team dear. Dr R. Schmutzler, of Loughborough University of Technology, has recently complained about the problem to the Ministers of Technology and Education. He tells of how he was forced to pay agency dues out of his own pocket; there was no provision for them in his research budget.

Those who try to do without the agencies find themselves at a disadvantage. Among other things, they are required to show that the rare chemicals they have ordered will be used only for research. The proof of this, Dr Schmutzler writes, is not easily demonstrated in letters to the customs or by appearance in person at the airport. Yet when the agencies handle the chemicals, no such rigorous investigation of the possibility of their misuse takes place. The customs will accept that drugs imported for laboratory research will be properly looked after only when the actual importing is done by an agency.

The agency will not, of course, question the motives of a university worker who orders a dangerous drug through them. The moral is therefore clear: research workers who are determined to supplement their salaries by selling drugs to swinging Londoners had better order through chemical import agencies. Only the honest man, insensitive to all insinuations of fraudulence, and disposed of a great deal of time, can handle imports of this kind for himself.

Dr Schmutzler goes on to compare the sympathetic attitude of the American authorities to the international traffic in valuable chemical samples, with the suspicion and lack of understanding shown by the customs over here. He and other frustrated research workers feel that it should surely be possible for them to obtain samples quickly, and without too much expense on the one hand, or trouble and even humiliation on the other.

## Loaves and Fishes

FOR an organization with a budget of only four hundred thousand pounds, the White Fish Authority certainly appears exceptionally versatile. In its research report, published this month, the Authority describes a cockle harvester, which will enable fishermen to exploit sublittoral beds where the density of the mollusc population is low, and gives an account of fish rearing experiments in Scottish lochs, and in tanks in which the water is heated by the effluent of nuclear power stations. This latter experiment is of unusual interest. It has been possible to rear a small number of sole to a marketable size in only one year, a process which would take three years in natural conditions. Other projects include the development of fenders, so that fish can be transferred from one vessel to another at sea. The authority also concerns itself with the processing of caught fish from their initial superchilling at 28° F, to their eventual appearance in specially concocted sausages and fish crisps.

As the report points out, most of the innovations in fishing techniques could have been produced fifty years ago. Conservatism, rather than lack of knowledge, prevented their development sooner. On the other hand, the authority is having to pioneer methods of basic research, in order to find out, for instance, how ships behave at sea in extreme conditions. The chairman of the research committee of the authority, Sir Fredrick Brundrett, has called—not for the first time—for a National Council of Marine Technology, saying that conditions in the fishing industry when the authority was founded had differed little from those obtaining in Galilee two thousand years ago. Perhaps a better comparison could have been drawn; even with the million pounds that Sir Fredrick wants for new research, the authority will be hard put to emulate certain achievements of those days. They did more with bread and fish than make sausages out of them.

## More Aid for Visual Aids

HARD on the heels of the newly formed National Council for Educational Technology, sponsored by the Department of Education and Science, comes the Industrial Council for Educational and Training Technology. This has been formed by four trade associations: the British Electrical and Allied Manufacturers' Association, the British Radio Equipment Manufacturers' Association, the Electronic Engineering Association, and the Scientific Instrument Manufacturers' Association. It has originally been the plan that ICETT should co-ordinate the production and use of technical aids in teaching, from machines to textbooks, but the formation of NCET will no doubt cause the Industrial Council to concentrate on the production of teaching aids, rather than their use. There have already been informal talks between the two organizations.

At present, ICETT is only qualified to work on behalf of manufacturers of hardware; discussions have been held with publishing and film associations. (Individual companies may not join the Council.) If ICETT can widen its interests to include both software and hardware, and if it can achieve close relations with NCET, we may hope to see more and better use of educational aids; this may become more and more important if the teacher shortage worsens.

## Improving Liaison

THE Vice-Chancellors Committee of the Confederation of British Industry (not to be confused with the Committee of Vice-Chancellors and Principals) has set up a working party under the chairmanship of Mr P. Docksey, Research Director of B.P. Ltd., to look into relations between universities and industrial research. Its terms of reference are "to study the existing relationships between universities and industry in the field of research, and to make recommendations".

Industrialists—and others—have a sneaking suspicion that much of the universities' research work is wasted. The decision to set up the working party reflects this concern and also the feeling that too few university graduates enter industry. It was prompted by the Sutherland report on relations between universities and Government research establishments. In addition to the chairman the working party consists of Dr A. A. L. Challis, Laboratory Director, I.C.I., Runcorn; Dr T. L. Cottrell, Principal of Stirling University; Dr K. Mather, Vice-Chancellor of Southampton University; Dr J. A. Pope, Director, Mirreles National Research Division; Dr J. S. Tait, Vice-Chancellor of The City University, formerly Northampton College of Advanced Technology; Mr T. A. Uthwatt, Director of Research, Mather and Platt Ltd.; and Dr F. A. Vick, Vice-Chancellor of the Queen's University, Belfast. Mr R. C. Griffith of the UGC, Mr J. Knox of the Ministry of Technology and Mr C. Jolliffe of the SRC will attend as observers. Also in attendance will be Dr A. V. Cohen of the DES, and Mr P. M. Knowlson of the CBI, who will act as secretary to the working party.

Among the areas covered by the working party will be collaboration between universities and industry, the educational need of the industrial research worker and the role of joint appointments. They will also investigate ways of improving universities' understanding of industry's needs and of making industry fully aware of university research. It is hoped that the working party will produce its report by the end of the year.

## ELDO Frustrated

IF the ELDO launchings are any guide, the weather in Australia does not seem to be all that the immigration authorities pretend. The partially successful launching on August 4 was the eleventh attempt to launch F6/1 from Woomera and most of the delays were caused by bad weather.

The purpose of the launching was to test the separation and ignition of the French second stage, Coralie, from the British first stage, Blue Streak. So far as is known, the French second stage separated but did not ignite. The reason given for the failure is that some of the components had waited so long to be launched that they were approaching the end of their design life.

It is not expected that this partial failure will hold up the programme and the F6/2 launching is expected in early November. ELDO hope to gather the additional information on the ignition of the second stage from this firing. At the same time, F6/2 firing will test the separation of the German third stage from the second stage. The F7 launch will be a test firing of the complete Europa 1 vehicle and is intended to inject a test satellite into orbit; it is still scheduled for mid-1968.

## A Rose by Any Other Name

CERA, the Civil Engineering Research Association, announced recently that it has changed its name to CIRIA, Construction Industry Research and Information Association. Its scope now includes research into all aspects of construction, and with the new terms for the grant to the association from the Ministry of Technology, money devoted to research will effectively double and that spent on information will effectively treble. The association's income in 1966 was almost £200,000 and with the promise of extra subscription already made by contractors, the new grant terms are expected to bring the association's income initially to about £300,000.

Under the new terms of the grant, the association receives £1 grant for every £1 raised on most of their industrial income, as long as it reaches £136,000 a year, with a maximum grant of £300,000. During 1966 the association spent £152,175 on direct projects. Among the projects supported was £14,398 for wind effects on buildings and other structures, £10,000 on striking of formwork, and £8,295 on criteria of concrete strength.

## Uncorking an Enzyme

from a Correspondent in Molecular Biology

THE activation of zymogens is known to involve the enzyme cleavage of one or more peptide bonds, and the generation of an active enzyme by this mechanism has sometimes been referred to as "uncorking". The most intensively studied activation of this type has been the chymotrypsinogen-chymotrypsin conversion. Several variants of chymotrypsin can be produced, depending on the conditions. The first product of activation (by trypsin) is  $\alpha$ -chymotrypsin, in which the peptide bond between residues 15 and 16 is cleaved. The further cleavage of the bond between residues 13 and 14 leads to the formation of  $\delta$ -chymotrypsin, with loss of a dipeptide, and the excision of a further dipeptide (147-148) produces  $\gamma$ -chymotrypsin (the most usual accessible form); by changing the conditions this can be converted reversibly into a further form,  $\gamma$ -chymotrypsin. In addition to the fission of peptide bonds, the chymotrypsinogen-chymotrypsin conversion is accompanied by certain physical changes, which have exercised many protein chemists in recent years.

Some direct observations of the differences between the different chymotrypsins and their parent zymogen now come from the crystallographic studies of Kraut *et al.* (*Proc. US Nat. Acad. Sci.*, **58**, 304; 1967). Although the resolution at this stage is only 5 Å, which means that the course of the polypeptide chain cannot be followed with certainty, it is still possible to draw several interesting, if tentative, conclusions, especially if reference is made to the recent 2 Å X-ray structure of  $\alpha$ -chymotrypsin of Matthews *et al.* The results demonstrate how X-ray studies can give relevant information to the protein chemist, without necessarily producing the complete structure of the molecule.

The clearest conclusion to emerge is the extensive similarity between chymotrypsinogen and the chymotrypsins. Thus activation does not involve any major rearrangement of conformation. A comparison between the zymogen and a  $\delta$ -chymotrypsin derivative reveals

the position of the break introduced into the chain, the difference between  $\pi$ - and  $\delta$ -chymotrypsins being also at this site. At the same time the peptide (residues 1-15) appears to coil back on itself. The remaining important difference occurs in another part of the molecule, in which a short segment of the chain is displaced, with consequent unmasking of a cavity. In this are located two out of the three inhibitor molecules which have been introduced into the crystals. This is evidently the basis of the "uncorking" process. It may be recalled that the chymotrypsin structure described by Matthews *et al.* (*Nature*, **214**, 652; 1967) reveals that the new N-terminal group which appears on activation forms an ion-pair with a residue at the active site, and this may be supposed to stabilize the native conformation.

Kraut *et al.* have also calculated difference-Fourier maps between the different chymotrypsin forms, and variously inhibited states. Apart from the removal of the dipeptides, the differences between the successive enzyme forms are very small and localized. Between active and inhibited  $\gamma$ -chymotrypsin one observes, in addition to the differences due to the inhibitor itself, only one local change, which it is suggested would arise from a movement, involving a displacement of some 6 Å, of one or two side chains only. This is evidently the extent of the "induced fit" effect, and it is interesting that it should be so small. It may well prove possible to define these details more precisely in terms of the 2 Å maps of Matthews *et al.* It will also, of course, be of great interest to have a precise description of the differences between enzyme and zymogen, and to reconcile the small structural differences between the four forms of the enzyme with reported variations in activity.

## Teaching Immunology

It is often difficult for people who have finished their formal education to obtain systematic instruction in a new subject. This is particularly true when the subject is changing rapidly, or is of general interest to specialists in other disciplines. Although the lectures given in technical colleges do something to meet the need, few people can find time to attend weekly lectures. In many subjects, indeed, the general point can be made that there is a need for intensive courses in which people could rapidly acquire knowledge of a subject after their periods of formal education.

The British Society of Immunology and the World Health Organization have recently attempted to provide something of the sort. With organization supplied by Professor Leslie Brent, they held a five day summer school in immunology at the University of Southampton. The object was to provide a summary of the present state of immunology for those who have to teach medical students, and for others who wished to know about the clinical and fundamental aspects of immunology. It was not intended primarily for professional immunologists. The course was attended by about fifty people, including some from Europe sponsored by WHO, and seems to have been hard work. Lectures during the day by invited lecturers were followed by demonstrations and discussion, and the broader aspects of the subject were covered by symposia in the evenings.

The intensive nature of the course and the fact that the participants were accommodated together in a Hall of Residence contrived to give participants the impression of going back to university, and it was possible to provide a reasonably balanced picture of the present state of immunology. Particularly valuable was the arrangement for making copies of the slides used by speakers, for distribution to people concerned with the teaching of immunology. Preparing slides on a range of topics is beyond the scope of any one department. The principles behind this symposium could well be applied in other disciplines, in an attempt to come to terms with the problems of further education in adult life.

## Metabolic Roles of Citrate

THE Biochemical Society held a symposium in honour of Sir Hans Krebs, FRS, at Oxford on July 14. Appropriately enough the topic for discussion was the metabolic roles of citrate. The many different disciplines represented illustrated the diverse ramifications that resulted from the original formulation of the tricarboxylic acid cycle some thirty years ago. Not even the imagination needed for such a discovery could have foreseen the widespread biochemical significance of the cycle.

The first two speakers described studies of purified enzymes of citrate metabolism: Dr P. A. Srere (Dallas) discussed whether kinetic studies on isolated enzymes at concentrations of  $10^{-10}$  molar or less gave a true picture of intracellular enzyme behaviour, since the concentrations of some enzymes at their intracellular sites were calculated to be as high as  $10^{-4}$  molar. Dr D. E. Atkinson stressed the importance of intracellular energy conservation for the control of the tricarboxylic acid cycle, and this was also the theme of Dr P. B. Garland's talk. Whereas Dr Atkinson in Los Angeles had studied purified enzymes and then extended the implications to more complex situations, Dr Garland in Bristol had proceeded in the reverse manner—it was gratifying that both approaches led to the same general conclusions. Dr J. Lowenstein (Brandeis) gave an account of the manner in which citrate linked the extramitochondrial synthesis of acetyl-CoA to the cytoplasmic synthesis of fat, a study which emphasized the significance of permeability barriers and membranes in the organization of cell metabolism. The same theme was continued by both Professor P. J. Randle (Bristol) in his description of the manner in which citrate formed in the mitochondria could control glycolysis occurring in the cytoplasm, and by Dr J. B. Chappell (Bristol) in describing the di- and tricarboxylic acid permeases of mitochondrial membranes. Professor M. Klingenberg from Munich gave an account of the adenine nucleotide translocase of the mitochondrial membrane which has extensive implications for the organization of intracellular metabolism.

The occasion marked the retirement of Sir Hans Krebs from the Whitney Chair of Biochemistry at the University of Oxford. At the conclusion of the symposium, Sir Hans modestly thanked the members of the Biochemical Society for the honour they had bestowed on him. It could not have been better deserved.

## Ribosomal 5S RNA

from a Correspondent in Biochemical Genetics

Two years ago Holley and his collaborators determined the base sequence of yeast alanine transfer RNA, the first RNA molecule to be sequenced. Subsequently Zachau and co-workers reported the sequences of two yeast serine transfer RNAs, Madison and co-workers that of yeast tyrosine transfer RNA and Khorana's group that of the yeast phenylalanine transfer RNA. In these cases the major problem lay in the isolation of several hundred milligrams of pure transfer RNA to sequence. The actual sequence determination was facilitated by the presence of unusual bases in these molecules, thereby helping to obtain overlaps of the fragments produced by digestion of the RNA with either pancreatic or T1 ribonuclease.

In this issue of *Nature* (page 735) Brownlee, Sanger and Barrell report the sequence of the *E. coli* 5S ribosomal RNA. This RNA occurs in the 50S ribosomal sub-unit and may be purified much more easily than a transfer RNA molecule. The techniques they used, which they themselves had developed, depend on handling very small amounts (about 100 micrograms) of RNA highly labelled with  $^{32}\text{P}$ . The difficulties in solving this sequence lay in its length of 120 nucleotides and in the absence of any unusual bases. To establish the sequence unambiguously therefore required the fractionation and sequence determination of many partial digestion products. The molecule, when folded up to allow some base pairing, looks quite different from a transfer RNA molecule. Of particular interest is the apparent homology between the two halves of the molecule. The authors suggest that this may be of evolutionary significance, though it is possibly more interesting to speculate that this homology reflects some symmetry in the construction of the 50S ribosomal sub-unit. This work represents a significant advance in the methodology of sequencing large RNA molecules.

## Feline Vision

from a Correspondent in Neurophysiology

THE receptive field of a unit in an animal's visual system has come to be known as that area of retina over which light stimulation causes a change in excitability of the neurone, usually measured as a change in the rate of production of action potentials. Since Hartline's classic work on the frog optic nerve, in which he discovered single fibres carrying responses to the "on" and "off" of a light stimulus, as well as fibres responding to both, a vast amount of information about the response properties of visual units has been amassed. Hubel and Wiesel, in particular (*J. Neurophysiol.*, **28**, 229; 1965), have investigated receptive field organization of units at several levels in the cat visual system, and have apparently demonstrated the existence of a hierarchy in which increasingly complex features of a visual stimulus are abstracted. There is some evidence that such a hierarchical organization also exists in the human visual system, and artificial pattern recognition devices have been designed to perform feature detection on a hierarchical basis.

Rodieck has recently found a new type of receptive field for ganglion cells in the cat's retina (*Science*,

**157**, 90; 1967). In general these have a centre-surround organization, in which the properties of the centre oppose those of the surround: if the centre responds to the on of a stimulus, then the surround responds to its off, and vice-versa. In two cats, however, one decerebrate and the other anaesthetized with nitrous oxide, Rodieck found two ganglion cells which responded to contrast anywhere within their receptive fields. These were between  $1.5^\circ$  and  $2.5^\circ$  in diameter (in terms of retinal angle) and possessed several unusual features. A black or white disk on a grey background, presented to the centre of the receptive field of either unit, caused an inhibition of firing; its removal was followed by reversion to the previous, maintained, firing rate, with no added "off" response. More complex stimuli, such as chessboard patterns, had similar effects: it seemed that contrast, and only contrast, was causing changes in firing rate. Movement of the stimulus at speeds of up to  $10^\circ/\text{sec}$  and rotations of the chessboard pattern had no effect, and it did not matter whether the stimulus was brighter or dimmer than the surround.

This discovery again poses the question of how much peripheral data processing is done in the mammalian visual system. Barlow and Hill have already shown that in the rabbit retina there are units at the ganglion cell level—and possibly as far out as the bipolar cells—which can detect movement of objects in the visual field in particular directions. Maturana, Lettvin, McCullough and Pitts have suggested that the frog's retina extracts four classes of feature from visual input, sending information to the optic tectum about small round objects ("bugs"), moving edges, contrast and "dimming" of stimuli. This peripheral organization of input is in marked contrast to the hierarchical organization described by Hubel and Wiesel for the cat, so the recent findings of Rodieck and also of Stone and Fabian (*Science*, **152**, 1277; 1966) serve to complicate the issue as they are not yet explained by the known details of retinal organization. Dowling and Boycott, working on the Primate retina (*Proc. Roy. Soc., B*, **166**, 80–111; 1966), found quite complicated patterns of synaptic organization which could well underlie similar functions in man and the rhesus monkey. They describe synapses involving, in the inner plexiform layer, bipolar, amacrine and ganglion cell processes. There seems to be ample opportunity for the lateral spread of excitation and inhibition necessary for movement detection, as well as in border, or contrast, enhancement. There is also the possibility of similar synaptic organization in the outer plexiform layer where horizontal cells might also be involved in the lateral spread of information between receptors.

## Nucleoli are Temperature Sensitive

from a Correspondent in Cell Biology

Simard and Bernhard (*J. Cell Biol.*, **34**, 61; 1967) have discovered that exposure of cultured mammalian cells to temperatures above normal selectively and reversibly affects the structure and function of nucleoli. In 1965 Gharpure reasoned that since DNA viruses fail to replicate in cells given a temperature shock (15 min at  $45^\circ\text{C}$ ) before infection, while RNA viruses replicate normally, there is some temperature sensitive step in DNA dependent RNA synthesis. Simard and

Bernhard followed up this suggestion, using electron microscopy combined with cytochemistry and autoradiography to examine the effect of supranormal temperatures on baby hamster kidney and rat embryo cells in culture.

The nucleoli of these cells cultured normally at 37° C have the four usual components, 150–200 Å granules and a loose reticulum of 50–80 Å fibrils, the nucleolonema both containing RNA, a proteinaceous amorphous matrix and associated chromatin with intranucleolar ramifications. Incubation at temperatures between 37° C and 41° C does not affect the cells but at 42° C a critical point is reached and even 15 min exposure causes striking changes in the nucleolus. The granules and intranucleolar chromatin are lost. The nucleolus exclusively consists of closely packed fibrils 60–100 Å wide. Incubation at 43° and 44° C has the same effect but above this the cells begin to die. Apart from these nucleolar lesions the cells are remarkably resistant to the elevated temperatures. The nuclei appear normal and in the cytoplasm the only changes are slight swelling of the endoplasmic reticulum and mitochondria. Moreover, the nucleolar lesions are fully reversible. Cells returned to 37° C, after 1 h at 42° C, grow happily, regaining the lost nucleolar components. In fact there is an excess of granules in the nucleoli of recovering cells.

At 42° C the incorporation of tritiated uridine into nucleolar RNA is reduced by 90 per cent whereas

nuclear uptake is reduced by only 20 per cent. This selective inhibition of nucleolar RNA synthesis strongly suggests that supranormal temperatures do not inhibit RNA polymerase. If this were the case all nuclear RNA synthesis should be equally affected. One possible explanation is that the nucleolar-associated template DNA is particularly heat labile.

When cells were pre-labelled with uridine and then exposed to a temperature of 43° C, the overall pattern of labelling in the nucleus was like that in cells maintained at 37° C. Thus the pre-labelled nucleolar granules cannot simply move into the nucleoplasm in response to the higher temperature. Simard and Bernhard propose that at 42° C and above the granules unfold to form fibrils by a transformation involving only configurational changes in the ribonucleoprotein molecules and when returned to 37° C the reverse occurs. This is in keeping with the precursor product relationship between at least some of the nucleolar fibrils and the granules which has been claimed by several workers. Recently, however, Hay and Gurdon (*J. Cell Sci.*, **2**, 151; 1967), who have studied the fine structure of the abnormal nucleoli in the so-called anucleolate mutant of *Xenopus laevis*, have questioned this relationship.

This point can be resolved by analysing isolated nucleoli, and Simard and Bernhard's temperature shock technique provides an interesting new approach for future studies of the various nucleolar components.

## Internal Structure and Energy Emission of Jupiter

by

R. SMOLUCHOWSKI

Princeton University  
Princeton, New Jersey

Jupiter emits much more energy than it absorbs. Explanations of the source of this heat depend upon our knowledge of its interior and of the behaviour of condensed matter at very high temperatures and pressures.

JUPITER emits more energy than it receives from the Sun. Gross and Rasool<sup>1</sup> in their theoretical study of the upper atmosphere of that planet concluded that the ratio of the emitted to the absorbed energy is about four, if the albedo is 0.47, while the more recent measurements of Low<sup>2</sup> indicate a ratio of about three. Thus an internal source of energy of nearly  $10^{33}$  ergs/year must exist. A concentration of radioactive elements characteristic of the Solar System would account only for  $5 \times 10^{-6}$  of the required energy. Similarly, the highest temperatures ever suggested for the inside of Jupiter are orders of magnitude too small to sustain exothermic nuclear reactions and so the gravitational field of the planet appears to be the most obvious source of energy<sup>1,2</sup>. The only other suggestion is that made by Dicke (personal communication), who has proposed that the energy release may be a consequence of a gradual decrease of the gravitational constant  $G$  which would lead to an increasing rate of rotation of the inner denser part of the planet with respect to the less dense outside mantle. This effect may result in generation of heat but so far the model has not been evaluated quantitatively.

Without going into the details of the radial density distribution in the planet, it is easily shown that a contraction of about 0.1 cm a year in the radius of the planet, which is  $7 \times 10^9$  cm, would yield the observed flux of energy<sup>2</sup>. In order to approach this problem in a more quantitative manner it appeared necessary to examine in some detail the existing models of Jupiter. What follows is the result of such an inquiry. This leads to a modification of the existing models, and also to an explanation of the observed energy flux; it appears at the same time to have a bearing on the origin of the large magnetic field of Jupiter and on the composition of its atmosphere.

### Models of Jupiter

Recent theories and discussions concerning the interior of Jupiter stem from the original work of De Marcus<sup>3</sup>, who assumed, in a first approximation, the existence of only hydrogen and helium on that planet. Using the best available equations of state, he arrived at a radial distribution of these elements which satisfied the known gravita-

Fig. 1. Schematic radial distribution of elements in Jupiter according to various models. ---, De Marcus; - · -, Peebles; —, modified.

tional multipole components, hydrostatic equilibrium, size and total mass. These results are roughly indicated in Fig. 1, which shows a small helium core surrounded by a thick layer of solid hydrogen in which the helium content decreases to nearly zero at the planet surface. At about 0.8 of the planet radius the solid hydrogen undergoes a transformation from a denser metallic phase to a less dense molecular phase.

Peebles<sup>4</sup> extended the De Marcus model by giving careful consideration to the atmosphere below the visible cloud layer and to the total helium abundance. He assumed that outside a small central core which may contain other elements besides hydrogen and helium the two elements are uniformly mixed—that is, that helium is sufficiently soluble in hydrogen and that convection currents effectively counteract any gravitational segregation. Peebles concluded that the atmosphere is most probably deep and adiabatic and that the mean atomic concentration of helium is 5 per cent, which corresponds to about 20 weight per cent. This model is also represented in Fig. 1. The low value of the critical temperature of hydrogen implies that there is probably a gradual change from a gaseous atmosphere to a liquid layer without there being a well defined surface.

The basic unavoidable weakness of these as well as of other models of planetary interiors has its roots in ignorance of the equation of state of condensed matter at very high pressure and at very high temperature. In particular, the melting points at high pressures are at best obtainable by extrapolation of low pressure experimental data by means of various semi-empirical relations such as, for instance, Simon's equation<sup>5</sup>. This is barely feasible even for the known molecular solid hydrogen; it is very difficult for the metallic form<sup>6</sup>, which has not been observed but the existence of which is almost certain. It is this gap in knowledge of the equations of state which leads to the coexistence of the De Marcus model, in which essentially all hydrogen is solid, and of the Peebles high temperature model, in which everything except perhaps a small inside core is assumed to be to some extent fluid so as to provide uniform mixing.

I now propose to show that a consideration of the hydrogen-helium equilibria leads to a model of Jupiter which is in a sense intermediate between the two described here.

### The Hydrogen-Helium Phase Equilibria

Schematically, the phase diagram of pure hydrogen at high pressures and at high temperatures, omitting the gaseous phase, consists of regions of solid molecular, solid metallic and liquid phases (see Fig. 2). The melting point  $T_M = 14^\circ \text{K}$  at low pressures is well known but the transition pressure  $P_t$  at  $0^\circ \text{K}$  is imperfectly known. Various extrapolations of the semi-empirical equation of state for the molecular solid and of the purely theoretical equation of state for the metallic solid yield values in the range

of  $1-3 \times 10^{12}$  dynes/cm<sup>2</sup> and a change of density of about 50 per cent<sup>4,5</sup>. Alder<sup>7</sup> questioned the validity of the extrapolated equation of state for the molecular form and, by means of entirely different considerations and in analogy to the known similar transition in solid iodine<sup>8,9</sup>, arrived at a transition pressure of  $20 \times 10^{12}$  dynes/cm<sup>2</sup>. Hitherto, all studies of the giant planets have been made using the lower values and I shall also assume a transition pressure of about  $2 \times 10^{12}$  dynes/cm<sup>2</sup>. It should be pointed out, however, that if the higher pressure turns out to be more correct, then drastic changes will have to be made in the variation with radius of both pressure and density for Jupiter and Saturn. Serious consequences for the temperature distribution will also follow because the normal and the radiative heat transfer rates must be expected to be quite different in the two phases. Some of these questions are discussed later on.

The location of the triple point  $S_1$  in Fig. 2 is rather uncertain. Simon's equation<sup>5</sup> can be used to extrapolate experimental points for  $P_t < 3.6 \times 10^9$  dynes/cm<sup>2</sup> or theoretical values for the constants of that equation can be used. It is also possible to calculate the melting temperature directly from the known fact that a solid melts when the root mean square amplitude of the atoms is about 0.2–0.25 of the mean radius of the unit cell<sup>10</sup>. Furthermore, the known Grüneisen constant and an approximate value of the Debye temperature which is obtainable for high pressures by various methods<sup>4,11</sup> can

Fig. 2. Schematic  $T$ - $P$  phase diagram of hydrogen: C, liquid molecular; D, liquid metallic; A, solid molecular; B, solid metallic (gaseous phase omitted). Lines  $\alpha$  and  $\beta$  illustrate the Peebles and the De Marcus models, lines  $\gamma$  and  $\delta$  the two modified models.  $P_t$  indicates the polymorphic transition pressure,  $T_M$  the normal melting temperature and  $T_s$  the surface temperature of the planet.

give information about the thermal expansion and vibration frequencies of solid molecular hydrogen near the transition pressure. While none of these methods is very reliable, most of the results lie in the range of 6,000–10,000° K. Because the transition pressure is probably not a steep function of temperature<sup>3</sup>, this temperature can be assumed also to apply to point  $S_1$ .

A much more difficult problem is the question of the existence or absence of a phase change between a molecular and a metallic liquid. So far, no such drastic polymorphic changes have been observed in any liquid. As mentioned here, melting occurs when the amplitude of atomic vibrations reaches a critical value such that the initial density is decreased by more than 30 per cent. This change is comparable with the change of density between metallic and molecular solid hydrogen, so that the chances of the existence of a liquid metal seem remote. On the other hand, a constant density curve starting in the  $P$ – $T$  diagram in the solid metallic phase would probably enter a metallic liquid phase given a sufficiently high  $T$  and  $P$ . Actually, the calculated slope of such constant density curves is not much higher than the slope of the theoretical melting curve of the metallic phase so that the point  $S_2$ , if it exists at all, must be expected to occur at an extremely high temperature.

Next, it is necessary to consider the influence of helium on the phase diagram of hydrogen. It is known that helium is very soluble in liquid molecular hydrogen<sup>12</sup> and this might apply also to the solid form. Theoretical estimates based on the known  $H_2$ – $H_2$ ,  $H_2$ –He, and He–He interactions<sup>13,14</sup> indicate a solubility not less than 50 atomic per cent. One would expect the melting point of this solution to be lower than that of pure molecular hydrogen. The situation with the metallic phase of hydrogen is quite different because noble gases are essentially insoluble in metals<sup>15</sup>. This can also be inferred from the known highly repulsive interaction between H and He (ref. 16). The problem changes considerably when a helium atom is embedded in metallic hydrogen which is being further compressed (J. J. Hopfield, personal communication). Such a compression increases the Fermi energy of the electrons in the metal while at the same time it lowers and narrows the potential barrier between the outside electrons of helium and the metal. Eventually an electron of the helium atom may tunnel into the metal and the positive helium ion will enter the metallic lattice to form an alloy. This is somewhat analogous to the formation of the known stable  $HeH^+$  molecule<sup>17</sup>. An exact solution of the problem is complicated, but an estimate of the required pressure can be made by calculating the density of the metallic hydrogen at which its known Fermi energy  $E_F$  or its crystalline potential  $E_s$  is comparable to the first ionization potential of helium. The value of  $E_s$  can be obtained from its relation to other quantities<sup>18</sup> or from the empirical form  $E_s = 2.5 (E_F)^{3/4}$  (C. Bocciaelli and R. F. Schwartz, personal communication). The result is a minimum pressure in the range of  $7$ – $11 \times 10^{12}$  dynes/cm<sup>2</sup>. It follows that at higher pressures there is a metallic hydrogen–helium alloy which, in accord with the usual behaviour of similar alloy systems, will have a lower melting temperature than pure metallic hydrogen.

### The Modified Model and the Contraction of a Solid Hydrogen Planet

This discussion of the hydrogen–helium system leads to the following conclusions concerning the interior of Jupiter. The transition from molecular to metallic hydrogen occurs at a temperature which lies either below or above  $S_1$  in Fig. 2. In the first case, there is a solid–solid interface. In the second, there is a solid–liquid interface. In either case the molecular hydrogen contains dissolved helium. The metallic layer is essentially pure hydrogen above that depth at which an alloy with helium

can exist. Presumably this helium reached the central regions of the planet at an early stage of the gravitational segregation of the planet when the central pressures were too low to produce metallic hydrogen. The central core is presumably mostly solid helium, but it may contain other heavier elements<sup>3,4</sup>. In the layer of liquid molecular hydrogen there are undoubtedly strong convective currents which lead to mixing and to a rather small temperature gradient. At the interface with the solid metallic form or with the solid molecular form, there has to be the usual boundary layer of essentially motionless liquid which, depending on the value of the assumed non-convective heat transfer rates, can be of the order of 100 m thick.

The melting temperature of a metallic solid solution depends on composition and thus it is not possible to specify the radius at which the He–H alloy becomes liquid. Assuming a required minimum pressure of  $11 \times 10^{12}$  dynes/cm<sup>2</sup>, the maximum radius of this layer is about one-half of the radius of the planet. There will be strong convective currents in this layer.

A schematic comparison of the three models here discussed is indicated in Figs. 1 and 2.

As a first approximation to the problem of the contraction of Jupiter, let us to begin with consider briefly a pure hydrogen planet of a uniform density  $\bar{\rho}$ , radius  $R$  and modulus of compressibility  $K$ . The total free energy of the system, which includes its gravitational energy  $\Omega$ , is lowered if  $\delta E$ , given by

$$\delta E = \delta \Omega - \delta W = -2\pi R \left( \frac{8}{15} \pi G R^3 \bar{\rho}^2 - 3K \Delta R \right) \delta R \quad (1)$$

is positive. Here  $\delta \Omega$  is the change in the total gravitational energy resulting from a decrease  $\delta R$  of the radius and  $\delta W$  is the simultaneous increase in the stored elastic energy produced by a previous strain  $\Delta R/R$ . Thus there is a maximum value  $\Delta R_{\max}$  for which  $\delta E > 0$  and a maximum value of energy which can be released  $(8/45) \pi G^2 R (\bar{\rho}^2) M^2 K^{-1}$ , where  $M$  is the mass of the planet. Because  $\Delta R_{\max}$  is proportional to  $\bar{\rho} M$ , it follows that  $\delta E$  is always positive for  $R$  greater than a certain critical value  $R_c \sim K^{1/2} (\bar{\rho})^{-1/2}$ . For most solids at high pressures  $K \sim \rho^2$  and thus  $R_c$  is a constant characteristic of the solid. For hydrogen, the appropriate values give  $R_c \sim 10^{10}$  cm which is close to Russell's upper limit for cold bodies as obtained by De Marcus from detailed calculations<sup>9</sup>. This assumes, of course, that the pressures are sufficiently low so that the planet can be treated as a solid rather than as a degenerate gas.

Clearly the assumption of a uniform density is not correct for a large body. Fortunately, both for the molecular and for the metallic phase of solid hydrogen, the relationship  $P = A(\rho^2 - \rho_0^2)$  is reasonably well obeyed in the range of the pressures which exist in more than 90 per cent of the volume of the planet. This leads to  $K = 2A\rho^2$  and to the well known Laplace radial distribution  $\rho(r) = \rho_c(L/r) \sin(r/L)$  where  $\rho_c$  is the central density and  $L^2 = A(2\pi G)^{-1}$  with  $L = 3.18$  and  $2.8 \times 10^9$  cm for the molecular and the metallic phase respectively. For  $R < 10^9$  cm, the radial gradient of pressure and of density is negligible for the effects discussed here. The Laplace distribution is not applicable near the surface of the planet, but its use is entirely satisfactory for the purposes of this study which deals primarily with the interior. Expressions for the change in the total gravitational energy  $\delta \Omega$  and for the change in the elastic strain energy  $\delta W$  can be obtained but are quite cumbersome. A good approximate value for  $\delta E$  can be, however, obtained using equation (1) and an average density in a sphere of radius  $R$ :  $\bar{\rho} = 3\rho_R L^2 R^{-2} [1 - RL^{-1} \text{ctg}(RL^{-1})]$  where  $\rho_R$  is density at the surface of the sphere. It is interesting that for a 10 per cent prestrain  $\Delta R/R$  in a hypothetical solid molecular hydrogen planet of the size of Jupiter, nearly 40 per cent of the evolved gravitational energy would be used for compressing the solid and the net rate of energy

emission would be  $\delta E/\delta R = 5 \times 10^{31}$  ergs/cm. The emission rate would be about four times greater for a hypothetical solid metallic planet of the same size.

In reality, however, Jupiter does have a metallic and a molecular phase and thus the gravitational contraction of a two phase model has to be considered<sup>19</sup>. The pertinent equations are

$$\delta\Omega = -\frac{3}{5} \frac{GM_c^2}{R_1^2} \left( R_1 \frac{\delta Q}{\delta R_2} - Q \frac{\delta R_1}{\delta R_2} \right) \delta R_2$$

where

$$Q = 1 - \frac{5}{2\gamma} + \frac{3}{2\gamma^2} + \frac{1}{\gamma^2} \left[ \frac{5(\gamma-1)}{2\beta^2} + \frac{1}{\beta^5} \right]$$

with  $\beta = R_1/R_2$ ,  $\gamma = \bar{\rho}_1/\bar{\rho}_2$ , subscripts 1 and 2 referring to the metallic core and the molecular mantle respectively and  $M_c$  being the mass of the core; further,  $\delta W = \delta W_1 + \delta W_2$  with  $\delta W_1 = 6\pi R_1 K_1 \Delta R_1 \delta R_1$  and  $\delta W_2 = 6\pi K_2 (R_2^3 - R_1^3)^{-1} (R_2^3 \Delta R_2 - R_1^3 \Delta R_1) (R_2^2 \delta R_2 - R_1^2 \delta R_1)$ . The requirement that the pressure should be the same on both sides of the boundary between the two phases leads to  $(\Delta R_1/R_1) [K_1 + \beta^3 K_2 (1 - \beta^3)^{-1}] = (\Delta R_2/R_2) K_2 (1 - \beta^3)^{-1}$ . There is a similar relation for  $R_1$  and  $\delta R_2$ . For  $R_1 = 5.6$  and  $R_2 = 7 \times 10^9$  cm, these equations give  $\delta E/\delta R_2 = 3 \times 10^{33}$  ergs/cm for a 10 per cent prestrain.

If it is now assumed that the radius of the metallic core  $R_1$  increases by  $\delta R_1$  at the expense of the molecular mantle without adjustment of the gravitational shrinkage, then  $\delta R_2 = (1 - \rho_1/\rho_2) R_1^2 R_2^{-2} \delta R_1 = (1 - \gamma) \beta^2 \delta R_1$  and

$$\frac{\delta\Omega}{\delta R_1} = \frac{3}{5} \frac{GM_c^2}{R_1^2} \left( 5Q + R_1 \frac{dQ}{dR_1} \right)$$

For the numerical values appropriate for Jupiter, this gives  $\delta E/\delta R_1 \sim 7.5 \times 10^{33}$  ergs/cm. There is also an additional term  $PdV$  caused by the change of density which is orders of magnitude smaller.

If the enlarged metallic sphere shrinks so as to reach the proper Laplace density distribution, additional gravitational energy will be released and a part will be used for increasing the stored elastic energy. The shrinkage is given by  $-(1-f^{-1})\delta R_1$  where  $f = x^{-2}[1 - 2xtg x + x^2(\sin x)^{-2}]$  with  $x = R_1/L$ . The effect is an increase of  $\delta\Omega$  by about 30 per cent. Thus the net available energy is about  $10^{34}$  ergs/cm with less than 5 per cent of it going into strain assuming, as before, a prestrain of 10 per cent. It should be emphasized that the magnitude of the assumed prestrain is such that its effect on the calculated energy release caused by phase change is less than that due to other approximations. As the phase change progresses, the requirement of hydrostatic equilibrium alters the density and pressure distribution in such a manner that the transition pressure occurs at progressively greater radii.

Thus it appears that a gradual increase of the metallic core at the expense of the molecular mantle of about 1 mm/yr would yield the required amount of energy for the presently observed rate of Jupiter's emission. It remains to explain this rate.

### The Rate of Energy Emission

Because metallic solid hydrogen does not dissolve helium, the phase change discussed here requires that helium dissolved in the molecular phase should diffuse away from the interface towards larger radii. The driving force for this diffusion is, of course, the consequential decrease of the total free energy of the system. The situation is relatively easy to evaluate if the diffusion occurs in solid molecular hydrogen for which the diffusion coefficient and its activation energy are known<sup>20,21</sup>. Unfortunately, there is no experimental information about the corresponding activation volume. In most metals, however, the activation volume is between 0.6 and 0.9 of the atomic volume<sup>22</sup>. For a pressure of  $2 \times 10^{12}$

dynes/cm<sup>2</sup> and a temperature around 3,500° K one obtains  $D = 3 \times 10^{-(10 \pm 1)}$  cm<sup>2</sup> per sec. The corresponding mean diffusion distance of 0.03–0.3 cm/yr is in the right range to account for the observed rate of energy emission. Peebles<sup>4</sup> has also estimated this diffusion coefficient using other approximations.

If at the molecular-metallic interface the molecular phase is liquid the situation is much more difficult to evaluate because experimental and theoretical knowledge of diffusion in liquids is not satisfactory<sup>23</sup>. Although diffusion in liquids near the melting temperature is in general appreciably faster than in solids, it increases more slowly with temperature than in solids because of the much lower activation energy<sup>23,24</sup>. Almost nothing is known about the influence of pressure on this diffusion. Nevertheless, on the basis of extrapolations based on estimated viscosities of liquid hydrogen at high pressures and temperatures, the expected diffusion rate of helium in liquid hydrogen is not in contradiction with the rates calculated here for the solid phase. It should be stressed that the convective currents in the liquid phase have little if any effect on the helium removal process because the critical diffusion occurs over distances several orders of magnitude smaller than the thickness of the stationary boundary layer.

The Elsasser<sup>25</sup> mechanism for generating magnetic fields in planets is based on the principle of a hydromagnetic dynamo, which entails rapid rotation of the planet and strong convective currents in an electrically conducting liquid. Clearly these conditions cannot be satisfied on Jupiter if only the molecular liquid is present because that must be strongly insulating. On the other hand, a liquid metallic hydrogen-helium alloy of the kind discussed here could explain the huge magnetic field, and the proposed size of this liquid layer is just about the same fraction of the total volume of the planet as of the Earth. The central location of the liquid core suggests a centrally located magnetic dipole and contradicts Warwick's earlier interpretation<sup>26</sup> of the decameter radio emission. It is supported, however, by the recent studies of decimeter radio emission<sup>27</sup> and by the studies of decameter radiation, if coexistence of axisymmetric dipole and quadrupole moments is assumed<sup>28</sup>. Such a situation could result from an uneven distribution of the solid phase; this would suitably perturb the roughly centrosymmetric pattern of the convective currents in the liquid. A similar mechanism could account for a local magnetic anomaly suggested by Ellis and McCulloch<sup>29</sup>.

An interesting consequence of the progressive enrichment of helium in the layer of molecular hydrogen is that it implies a higher helium to hydrogen ratio in the atmosphere proper. This enrichment would help to account for the mean molecular weight deduced by Öpik<sup>30</sup> of 4.3, or by Baum and Code<sup>31</sup> of 3.3, without invoking rather complicated mechanisms. It is also suggested by some recent studies of the Jovian atmosphere<sup>32,33</sup>.

Finally, what if the higher rather than the lower transition pressure from the molecular to the metallic form of hydrogen turns out to be more correct? The main consequence would be the presence of a small metallic core made of a presumably helium rich hydrogen-helium alloy. This core would be liquid and would be surrounded by a thick solid molecular hydrogen mantle. It is not certain whether this liquid metallic core would be sufficiently conductive or sufficiently large to account for the huge magnetic field.

### Conclusions

The modified "intermediate" model of the interior of Jupiter described here has certain physico-chemical advantages compared with the earlier models and several interesting consequences as well. Unfortunately, present quantitative uncertainties about the hydrogen-helium

system and the heat conduction and convection in that system make detailed calculations premature. Careful comparison with the known multipole gravitational moments is needed to confirm the presence of higher helium content in the outer layers of the planet. The fair degree of agreement between the calculated and the observed rate of energy emission, although not conclusive, suggests that the proposed mechanism may indeed be operative.

I wish to thank my colleagues Professors Daniels, Deutsch, Dicke, Hopfield, Keil, Peebles and Wigner for many interesting discussions and for advice.

## Pre-Columbian Maize in Southern Africa

by  
M. D. W. JEFFREYS

University of Witwatersrand,  
Johannesburg

Maize is indigenous to America and can only be propagated by man. Its presence in Southern Africa in the fourteenth century is therefore particularly intriguing.

MAIZE is an American plant which does not propagate itself, so that its presence is due to human agency. There is, however, evidence for the presence of maize in southern Africa, south of a line from the mouth of the Zambezi in the east to the mouth of the Cunene in the west, which raises several questions about the human agency responsible.

This article comments on observations made in the early sixteenth century which indicate that there was maize in southern Africa when the Portuguese arrived. The same evidence also suggests that people responsible for introducing maize to the coastal regions of eastern Africa were Arabs; that migrating African tribes which had obtained maize from the Arabs introduced it to the interior; and that this introduction of maize occurred before Columbus discovered America. I am not here concerned with the agency initially responsible for bringing maize from America to the Old World.

### European Evidence

The first European to reach Mozambique around the Cape was Vasco da Gama, who recorded *milho* there in March 1498; in an account of the capture of two boats in the Mozambique channel, da Gama wrote: "In the one we took, we found seventeen men, besides gold, silver and an abundance of maize (*milho*) and other provisions". This record, however, was not published until 1512.

The word *milho* is of interest because it is the standard Portuguese name for maize and was used for maize in the early records of Portuguese administration on the east African coast. As early as 1506 at Sofala<sup>2</sup> the following entry occurs in the King's Treasury: "... merchandise and items were spent in buying one hundred and seventy-seven bags of maize with fifteen heads of maize to each bag for the maintenance of the people of this fortress". An entry

on September 1, 1511<sup>3</sup>, which includes reference to sorghum and rice, further clarified the meaning of *milho*: "Bertolemeu Perestrello, factor of this fortress of Sofala ... order you Troylos Bramdam ... to give ... to these forty-nine people ... four hundred *alqueires* of unhusked rice and fifty four *alqueires* of maize (*milho*) and nine *alqueires* of kaffir corn (*mexoeira*) ...". On *mexoeira*, Junod<sup>4</sup> noted: "The word ... nowadays designates the small grey kaffir corn in Lourenço Marques". Kaffir corn is a South African name for *Sorghum vulgare*.

The account of an introduction of maize by the administrator of the Dutch East India Company to the Cape will be found in Van Riebeeck's journal. He expected to find maize in Angola and finally obtained it from West Africa. His Guinea slaves understood its cultivation, which was unknown by his Dutch farmers. To describe this cereal Van Riebeeck used variants of the word *milho*, namely *mily* and *milie*. Such terms for maize are found in use only in South Africa.

In January 1658 Van Riebeeck<sup>5</sup> sent a vessel to Angola to search, among other things, for "maize". Van Riebeeck in his journal<sup>6</sup> had written *milie*, not "maize". In July 1658<sup>5</sup> Van Riebeeck encouraged the planting of maize or "Turkish wheat obtained from Guinea" as the "right time for planting maize is now approaching and the slaves know well how to do it". Van Riebeeck's words were "*mily ofte Turcx taruw*". Burt-Davy<sup>7</sup> held that *mielie* "is derived from the Portuguese word *milho*, from the Latin *milium*, the name for millet".

Van Riebeeck, who joined the Dutch East India Co. in 1639, was brought into contact with Portuguese trading to Africa and the East in the course of his employment. His use of the terms *mily* and *milie* reflect the Portuguese usage of *milho* for maize in the seventeenth century.

The term used today by the Portuguese for maize is still *milho*, and it has been in continuous use. Indeed Santa

Rosa de Viterbo<sup>8</sup> had no hesitation in supposing that the use of the word *milhom* in 1289 referred to maize.

Portuguese documents of the sixteenth century record two Bantu names for a maize-meal loaf. In both Bantu languages there is a separate name for a sorghum-meal loaf. Dos Santos was in Sofala in 1586 and wrote<sup>9</sup>: "The bread commonly eaten in Sofala is made of rice and millet (*milho*) mixed and made into cakes which they call *mocates*". The Manganja language is spoken in the Zambezi valley and the Manganja word for maize-meal loaf is *mkate*. Scott noted<sup>10</sup>: "... the real *mkate* is a roll compounded of maize flour mixed with bananas and honey". The Manganja name of a roll made with sorghum is *nsima*.

When the Santo Alberto foundered in 1593 off the Natal Coast, the pilot's record of the disaster<sup>9</sup> noted: "In exchange for a few tacks, they [the Negroes] gave a quantity of milk and cakes of millet (*milho*) which they call *sincóá*". The Nguni tongue spoken in Natal is Zulu and the Zulu word for a maize-meal loaf is *isinkwa*. The Zulu name for a sorghum-loaf is *isigwamba*. The Nguni example is particularly interesting because the Nguni had come down from central Africa without European contacts. It is impossible to dismiss these two words for a maize-meal loaf, which were recorded phonetically, as aberrations on the part of otherwise highly factual writers.

### The Arab in the Indian Ocean

The question arises of the agency by which maize came to the east African coast. The names used by the coastal Negroes for maize suggest an answer. Many tribal words for maize among the coastal natives consist of a word compounded of their name for sorghum and the name *Manga*. I<sup>11</sup> have shown that *Manga* is a Bantu corruption of Mecca and hence that *Manga* refers to Arabia. Here are examples of such Bantu maize names.

Livingstone, on Nyahasene island in the Zambezi, wrote in his journal of August 1858<sup>12</sup>: "*Mapira* is the name of the large millet or sorghum and *Mapira manga* of Maize (foreign *mapira*)". Posselt<sup>13</sup>, a Rhodesian Native Commissioner, stated that the Chitonga around Sofala and up the Pungwe and Sabi rivers likewise call sorghum *mapira*, and maize *chipira manga* or the sorghum of *Manga*. The *Dicionário Português-Cinyanja*<sup>14</sup> gives *cimanga* as *milho* among the Nyanja of Mozambique. The Gaza people call maize *kimanga*. Doke<sup>15</sup> showed that the Talakundra, Lilima, Kalanga and Numbzya of Rhodesia call maize, *tsimanga*. These *manga* maize names indicate that the Arabs introduced maize<sup>16</sup>. It should also be borne in mind that "1502-1509 Portugal wrests control of Indian Ocean and East African coast from the Arabs"<sup>16</sup>.

These *manga* names are of little help in determining a date for the entrance of maize into Southern Africa, but the names used by Nguni migrants, by tribes in contact with Nguni migrants and by baVenda migrants offer datable information.

### Nguni Migrants and Tribes in Contact with Them

Historical tracing of Bantu word meaning is difficult. Three assumptions, however, may be made. First, where there are two groups of the same stock separated from each other in space and time and each has a similar name for a cereal, it is reasonable to assume that the cereal arrived before the separation took place and that the migrating group departed with both the grain and their common name for it. Secondly, where indigenous people through whom migrants pass give their nickname for the migrants to a cereal, it is feasible to presume that the indigenous group acquired this cereal from the migrating group. Thirdly, where a group which has recently arrived in an area has a cereal name which is not used by any of the group's present neighbours it is probable that their neighbours had the cereal before they arrived.

In comparatively recent times the Nguni migrated into southern Africa. The Zulu, a Nguni group, probably left Nyasaland some 500 years ago, according to Bryant<sup>17</sup> (and by "Nyasaland we mean the Uganda-Kenya region"). Bryant's date places this migration at about 1450 A.D. My own researches put the date at about 1400 A.D.

The Nguni name for maize is *umbimla*. Bryant<sup>17</sup> stated that the word is "obviously of the same derivation as the common East African *mapira* (an *r* elsewhere always becomes an *l* in Zulu and a *p* frequently a *b*) a name applied there, sometimes to maize (for example, in Senga, on the Zambezi), in Tanganyika colony and other tongues..." The conclusion is that the Nguni had maize and their maize name before they migrated. Here one is dealing with a time that is pre-Columbian.

As the Nguni traversed Bantu tribes which were already settled south of them the Nguni would be associated with the arrival of maize among these tribes, as a study of maize names among tribes penetrated by the Nguni suggests.

South of the Zambezi-Cunene line live the Sotho and Sigwanba, who had long preceded the Nguni. These tribes have been in continuous first hand contact with the Nguni through the Transvaal Ndebele and the baKoni, who<sup>17</sup> were an Nguni splinter that became "Sutuized". Among these Sotho and Sigwamba, maize names<sup>18</sup>, are respectively *ma-vele* and *se-fela*. The Mpoche, a branch of the Transvaal Ndebele, call maize *se-peala*. Such names are phonetic dialectical variations of *um-bila*. As maize would be a new crop to the Bantu into whom the Nguni erupted, it is clear that the Bantu, on taking over maize from the Nguni, adapted the Nguni maize name.

### Tribes in Contact with the Nguni

Among other tribes in southern Africa maize names are compounded of *b-n*, *p-n* and *po* stems which can be equated with the Nguni. Thus the Nguni who settled in Rhodesia under Mzilikazi about 1823 are called<sup>19</sup> *ma-Pune* by the Chishona. According to van Warmelo<sup>20</sup>, the Zulu are called *ma-Pone* by the Basuto and *ma-Bunya* by the baVenda. Earlier one finds the name Kabona given<sup>21</sup> to the Nguni by the Hottentots.

I have shown that African tribes are referred to by their salutation term<sup>22</sup> and this is how this basic *b-n*, *p-n* name came to be conferred on the Nguni. The Nguni salutation term is *sa-Kubona*, that is, the Kabonas or Boona or even Poona people, for *b* and *p* are phonetically interchangeable. The Nguni are known to many of the Bantu tribes through whom they migrated north of southern Africa by a name containing the stems *b-n*, *p-n* and *po*, and among these tribes one finds maize names with these *b-n*, *p-n* and *po* stems.

A reasonable explanation for such names is that these tribes obtained maize from the people whom they called by names containing the *b-n*, *p-n* and *po* stems, in which case maize reached these inland Bantu from the north long before da Gama had reached Mozambique in 1498 and before Columbus was born.

In the area between the Sabi and Pungwe rivers in Rhodesia, an area traversed by the migrating Nguni, Johnston<sup>18</sup> gives *ma-bonere* as the maize names among the Cindau, Citeve and Citomboyi. Also<sup>18</sup>, among the Bechuana-land tribes one finds the Sikolo with *m-bonyi* for maize and the ba-Mangwato with two names for maize, *m-bonyi* and *mo-vopu*. Among the ma-Rutze the maize name is *m-boni*<sup>23</sup>. The baSutho, who have long been in contact with the Nguni, call maize<sup>7</sup> *poone* while the Xosa name for maize is *boona*.

The ba-Sotho tribes<sup>24</sup> were in their present habitat before 1300 A.D. Among the baKwena, a Sotho tribe, are settled the baPo. These consist of Nguni groups who<sup>24</sup> migrated thither from Zululand around 1600 A.D. The baKwena word for maize is *m-mopo*, a name derivable from *maPo*, the Sotho name for these Nguni. It is difficult

to explain this *m-mopo* maize name in any other way than in the light of the introduction of maize to the baKwena by these Nguni. The be-Chuana call maize *m-mopo*<sup>25</sup>.

### The baVenda Migrants

The baVenda, like the Nguni, have come from the north. Gottschling<sup>26</sup> concluded that the baVenda "originally came from the great lake regions of eastern central Africa". With this origin for the baVenda their maize name is revealing. Though the present baVenda in the Transvaal are surrounded by people who call maize *um-mbila* and though the baVenda name for the Nguni is maBunya, yet the baVenda maize name is<sup>18</sup> *cikoli*. But maize names around the great lake regions also include the *k-l* or *k-r* stem. Thus it appears that the baVenda when they migrated had, like the Nguni, maize and their own name for it. Because no tribe in southern Africa has to my knowledge a name connected either with the baVenda or with *k-l* or *k-r* stems, I conclude that southern African Bantu encompassing the baVenda had acquired maize and their maize names before the baVenda had arrived. Consequently the baVenda arrived in southern Africa some time after the Nguni.

Von Sicard<sup>27</sup> reckoned that the baVenda reached the Zambezi in the fourteenth century; I think this date is a little too early. Nevertheless the date is clearly pre-Columbian.

From the above evidence it is clear that maize had reached southern Africa before Columbus had discovered the New World.

## Intensity of the Earth's Magnetic Field in the Geological Past

by

MIROSLAV KRS

Institute of Applied Geophysics,  
Podbělohorská silnice 47,  
Praha-Smichov,  
Czechoslovakia

The intensity of the geomagnetic field in Central Europe during the Permo-Carboniferous, Permian and Plio-Pleistocene did not differ appreciably from the present day intensity.

KNOWLEDGE of the intensity of the geomagnetic field during the geological past is necessary to understand the nature of the geomagnetic field itself, as well as to study the magnitude of remanent magnetization of rocks and minerals. The spatial distribution of the intensity of the geomagnetic field during various geological periods on the individual continents would provide further much needed data for verifying the continental drift theory. For such a study accurate data are needed, which can then be averaged out to exclude such effects as the secular variation of the geomagnetic field. The archaeomagnetic method of Thellier<sup>1</sup> has provided data on the intensity of the geomagnetic field in the historical past. Thellier's method of stepwise heating makes it possible to identify the intensity of the geomagnetic field in the geological past, but the demands placed on the magnetic properties of natural materials by such studies are very high. First the natural remanent magnetization  $J_n$  of samples must be of thermo-remanent origin, the samples must be palaeomagnetically stable (both in direction and modulus of  $J_n$ ) and must not undergo undesirable phase transition during the heating process in the laboratory. I found

three natural materials for determining the intensity of the Earth's magnetic field in the geological past.

Natural cassiterites with iron ions bound to the lattice frequently show outstanding palaeomagnetic stability<sup>2</sup>. The stepwise heating method of two very fine grained cassiterite aggregates was used to derive the intensity of the geomagnetic field in the Permo-Carboniferous. This was found to be  $0.55 \pm 0.06$  oersted at the Horní Slavkov locality (lat.,  $50-12^\circ$  N.; long.,  $12-80^\circ$  E.) in Western Bohemia. As the cassiterite was derived from a greisen type of mineralization this value probably corresponds to the mean intensity of the geomagnetic field with the effects of secular variation averaged out. Detailed tests of palaeomagnetic stability and "mineralogical stability" were carried out on these aggregates<sup>3</sup>. Other samples of cassiterite (from Bolivia, Swaziland and the Far East) were not fully stable and underwent partial phase transitions. They were either not monomineralic aggregates or contained undesirable heterogeneous admixtures of other minerals.

Some ignimbrites are also suitable because they are formed by the settling of clouds of acidic ash at a tempera-

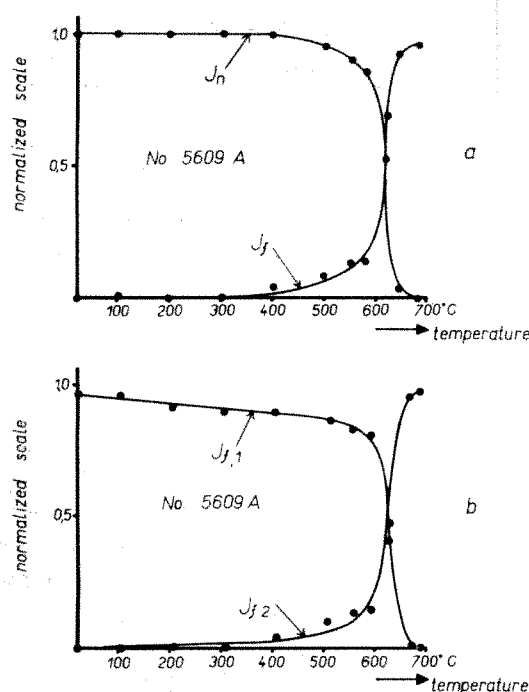

Fig. 1. *a*, Decay of natural remanent magnetization ( $J_n$ ) and acquisition of partial thermo-remanent magnetization ( $J_f$ ) of the ignimbrite sample No. 5609 A, north-east Bohemia, Hynčice, near Broumov. *b*, Decay of thermo-remanent magnetization produced in the laboratory ( $J_{f,1}$ ) and repeated acquisition of partial thermo-remanent magnetization ( $J_{f,2}$ ) of the same sample.

ture above the Curie temperature of the iron oxides contained therein<sup>4</sup>. As the porous ignimbrite cooled down the iron oxides acquired a thermo-remanent magnetization and (provided there was constant access to air) became "mineralogically stabilized". Fig. 1 shows representative graphs of thermal demagnetization ( $J_n$ ) and magnetization ( $J_f$ ) in a laboratory magnetic field of intensity  $F_L$  equal to 0.48 oersted, of an ignimbrite sample from Hynčice, near Broumov, north-east Bohemia. The direction of remanent magnetization of partially demagnetized samples remained identical with the  $J_n$  directions during thermal demagnetization, the declination amounting to  $192^\circ$  and the inclination to  $-3^\circ$ . These values correspond to the Permian palaeomagnetic directions in Central Europe. It thus appears that the  $J_n$  directions of samples examined here do not show any marked evidence of chemical, viscous or other magnetization that might have altered the original magnetization of the ignimbrite. If the thermo-remanent magnetization formed in the samples in a laboratory field  $F_L$  is designated by the symbol  $J_f$ , and the intensity of the geomagnetic field acting at the time of cooling of ignimbrite by  $F_0$ , then  $F_0/F_L = J_n/J_f$ . After laboratory magnetization, the samples were again demagnetized ( $J_{f,1}$ ) and remagnetized in a laboratory field ( $J_{f,2}$ ). The results shown in Fig. 1 suggest that the samples were mineralogically stable; similar data were obtained from seven other samples of ignimbrite from the same locality. The results were used to calculate the intensity of the geomagnetic field during the Lower Permian and it was found that  $F_0$  had the value of  $0.50 \pm 0.03$  oersted for the locality Hynčice, near Broumov (lat.,  $50.63^\circ$  N.; long.,  $16.30^\circ$  E.), in north-east Bohemia. In view of the relatively short period of cooling of the ignimbrite, the value undoubtedly represents the geomagnetic field at one instant and the field has been influenced by such factors as secular variation. Ignimbrite samples from France (Nideck) were investigated, but they either displayed slight phase changes in the course of the laboratory process or their  $J_n$  contained a large proportion of non-thermo-remanent magnetization.

The best archaeomagnetic samples are porcellanites, natural baked earths and palaeoslags. These rocks are formed under natural conditions, frequently in large amounts, through the thermal alteration of loams and loesses by spontaneous combustion of coal seams during the geological past. Spontaneous combustion of coal can occur wherever air enters a coal seam exposed by landslides, erosion or dislocation of overlying strata. In these rocks the  $J_n$  is of thermo-remanent origin and the magnetization of the minerals was stabilized at the time of thermal alteration. The carriers of  $J_n$  of these rocks are composite mixtures of iron oxides which give the rocks their typical red or purple colour. The loam rocks give rise to porcellanites, and the loesses to natural baked brick loam. If the temperature at the time of alteration exceeds  $1,400^\circ$ – $1,500^\circ$  C, palaeoslags are formed; these pass through a liquid stage. Fig. 2 shows an example of a curve of thermal demagnetization ( $J_n$ ) and magnetization ( $J_f$ ) of porcellanite from the locality, Březno, near Postoloprty, north-west Bohemia. In that region, in the so-called Chomutov-Most-Teplice coal basin, the strata overlying seams of soft coal contain dozens of extensive occurrences of porcellanite, natural baked brick loam and palaeoslag which were formed at different periods within the Plio-Pleistocene<sup>5</sup>. Fig. 2 also shows curves of repeated thermal demagnetization ( $J_{f,1}$ ) and magnetization ( $J_{f,2}$ ). The linear relationship follows from plots of  $J_n - J_f$  and  $J_{f,1} - J_{f,2}$ . Fig. 3 shows histograms of  $k$  and mean values of  $k$  for the localities studied,  $k$  being equal to  $J_n/J_f$ . Numerical data are summarized in Table 1. Samples from the locality of Vtelno near Most contained only reverse directions of  $J_n$  both for the porcellanites and for palaeoslags. Samples from Tušimice and Březno, near Postoloprty, contained only normal directions of  $J_n$ . The table shows that the intensity of the geomagnetic field within the Plio-Pleistocene showed variations in intensity, similar to values found archaeomagnetically<sup>6</sup>. These differences are probably caused by secular variation of the geomagnetic field. In all samples (the data for which are shown in Table 1) the relationship of  $J_n$  to  $J_f$  is linear. In typical representatives, the linearity of  $J_{f,1}$  to  $J_{f,2}$  was also confirmed, the  $J_{f,1} - J_{f,2}$  lines subtending  $45^\circ$  angles with the abscissae and the ordinates; this suggested that repeated laboratory procedure did not bring about any phase transitions in the samples<sup>7</sup>.

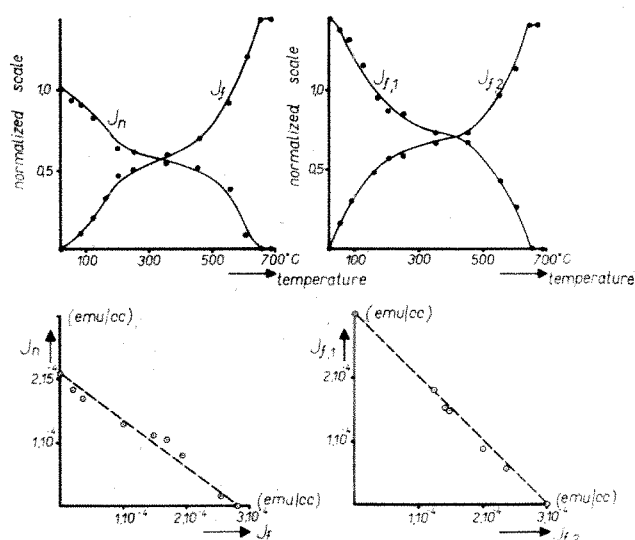

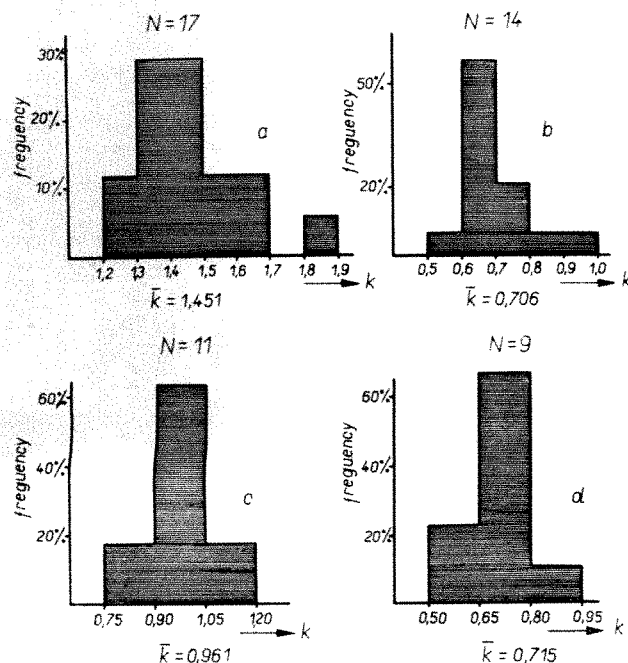

Fig. 2. Decay of remanent magnetization and acquisition of partial thermo-remanent magnetization of the porcellanite sample, No. 5878 A, north-west Bohemia, Březno, near Postoloprty. The symbols  $J_n$ ,  $J_f$ ,  $J_{f,1}$ , and  $J_{f,2}$  the same as in Fig. 1.

Table 1. INTENSITY OF THE GEOMAGNETIC FIELD IN THE PLIO-PLEISTOCENE DERIVED FROM THERMO-REMANENCE OF PORCELLANITES AND PALAEOSLAGS COLLECTED IN THE CHOMUTOV-MOST-TEPLICE COAL BASIN, NORTH-WEST BOHEMIA (MEAN GEOGRAPHICAL CO-ORDINATES: LAT., 50°38' N.; LONG., 13°37' E.)

Locality	$\bar{k}$ (mean ratio of $F_0/F_L$ )	S.D.	No. of samples analysed	Intensity of the geomagnetic field (in oersteds)	Mean direction of $J_n$	
					Declination	Inclination
Tušímece	1.451	$\pm 0.173$	12 porcellanites and 5 palaeoslags	$0.699 \pm 0.083$	$339.5^\circ$	$76.2^\circ$
Březno, near Postoloprty	0.706	$\pm 0.094$	9 porcellanites and 5 palaeoslags	$0.340 \pm 0.045$	$352.6^\circ$	$55.4^\circ$
Vteln, near Most	0.961	$\pm 0.103$	11 porcellanites	$0.463 \pm 0.050$	$209.1^\circ$	$-60.1^\circ$
	0.715	$\pm 0.119$	9 palaeoslags	$0.345 \pm 0.057$		

Fig. 3. Frequency histograms of  $k$  ( $\bar{k}$  the mean value).  $N$ , Number of samples analysed from the localities in north-west Bohemia: a, Tušímece; b, Březno, near Postoloprty; c, Vteln, near Most (porcellanites); d, Vteln, near Most (palaeoslags).

The intensity of the geomagnetic field determined for the Permo-Carboniferous and for the Lower Permian for Central Europe on the basis of an analysis of the thermo-remanence of cassiterite and ignimbrite is similar and

does not appreciably differ from the present day field intensity, which is 0.482 oersted. These data can be compared with some previous calculations<sup>8</sup>. Similarly, the intensity of the geomagnetic field during the Plio-Pleistocene, determined on the basis of an analysis of thermo-remanence of fifty-one samples of porcellanites and palaeoslags, does not differ much from present day intensity which is in agreement with the results reported from New Mexico, Arizona<sup>9</sup> and from Armenia<sup>10</sup>. At the same time, some cassiterites and ignimbrites can be used for such tests. Cassiterites with the necessary properties are relatively rare, but ignimbrites are common in New Zealand, in Western USA, Mexico, Peru, Italy, Indonesia and elsewhere. Without exception, porcellanites and palaeoslags prove ideal for the determination of intensity of the geomagnetic field during the geological past. These materials frequently occur in various coal basins, but the great problem is to determine the age of the thermal alteration.

I thank Professor A. E. M. Nairn and Dr M. Westphal for samples of ignimbrite, and Dr K. Tuček for samples of cassiterite. I also thank Professor M. G. Rutten, the director of the Swaziland Geological Survey and Mines Department, and Dr D. M. Pechersky.

## Initiation of Vinyl Polymerization by Manganese Carbonyl and Carbon Tetrachloride

by  
L. I. B. HAINES  
A. J. POË

Department of Chemistry,  
Imperial College,  
London

Kinetic investigations of the reaction of manganese decacarbonyl have shown that two rate determining processes operate; one involving the formation of a reactive intermediate, which may be a pair of  $Mn(CO)_5$  radicals trapped in a solvent cage, the other involving the dissociation of a carbon monoxide molecule. Kinetic data are used to reinterpret the results of Bamford *et al.* on the use of mixtures of manganese carbonyl and carbon tetrachloride to initiate vinyl polymerization.

BAMFORD *et al.* have suggested<sup>1,2</sup> that the free radical polymerization of methyl methacrylate, in the presence of mixtures of manganese decacarbonyl and carbon tetrachloride, is initiated by  $CCl_3$  radicals produced by the reaction of carbon tetrachloride with  $Mn_2(CO)_{10}$ , the latter being formed by a slow, rate-determining dissociation of carbon monoxide from manganese carbonyl. An initiation reaction involving manganese-manganese

bond fission and the formation of  $Mn(CO)_5$  radicals has been specifically excluded. The whole question of the formation of pentaco-ordinate radicals of this kind, either as stable products of reaction or as reactive intermediates during reaction, is still subject to considerable confusion.

The existence of  $Mn(CO)_4L$  ( $L = PPh_3, PEt_3, SbPh_3$ ) (ref. 3) has not been confirmed<sup>4-6</sup>, and the only well authenticated pentaco-ordinate radical appears to be  $Mn(CO)_4$ ,

(AsPh<sub>3</sub>) (ref. 6). Basolo and Wawersik concluded that substitution reactions of manganese carbonyl go by means of the rate determining dissociation of carbon monoxide, and that homolytic fission of the manganese-manganese bond does not occur. Quite detailed kinetic investigations, however, have suggested that substitution, oxidation, and decomposition reactions of manganese decacarbonyl, in inert solvents, do involve homolytic fission of the manganese-manganese bond as the rate determining step, the two Mn(CO)<sub>5</sub> radicals formed being trapped together in a solvent cage<sup>7</sup>.

We have now found from further investigations that, for the substitution reactions with triphenylphosphine, the dissociation of carbon monoxide contributes an additional rate determining step (unpublished results). All the reactions are first order in the concentration of manganese carbonyl. The rate of substitution by triphenylphosphine increases with [PPh<sub>3</sub>], but reaches a limiting rate at high concentrations. The rate of decomposition of manganese carbonyl in solvents, saturated with oxygen, is slower than the limiting rate of substitution with triphenylphosphine at the same temperature.

The reaction with iodine produces iodopentacarbonylmanganese in up to 100 per cent yield. The pseudo first order rate constant for this reaction is of the form  $k_{\text{obs}} = k_1 + k_2[\text{I}_2]$ , where  $k_1$  is equal to the rate of decomposition in the presence of oxygen at the same temperature. The second order constant is assumed to be due to direct bimolecular attack on the complex by iodine.

Under one atmosphere of carbon monoxide, the rate constant for the substitution reaction decreases to the same value as for the reaction with oxygen or for the [I<sub>2</sub>]-independent reaction with iodine. One atmosphere of carbon monoxide has no effect on either  $k_1$  or  $k_2$  for the reaction with iodine. This suggests that the reaction with oxygen, and the [I<sub>2</sub>]-independent reaction with iodine, proceed by the same mechanism, namely homolytic fission of the manganese-manganese bond, but that the substitution reaction with triphenylphosphine, in the absence of carbon monoxide, can also proceed by way of a slow dissociation of carbon monoxide from the complex. The ratio of the rate constants for reaction with high concentrations of triphenylphosphine to those for the oxidation reactions is constant at  $1.37 \pm 0.10$  in a temperature range of 80–135°C. This means that activation energies for the manganese-manganese bond fission and for carbon monoxide dissociation are essentially the same (37 kcal/mole<sup>7</sup>). Both mechanisms should lead to the same type of dependence on [PPh<sub>3</sub>].

These results, which will be reported in detail elsewhere, lead us to comment on the mechanism of the initiation of vinyl polymerization by mixtures of manganese carbonyl and carbon tetrachloride. The similarity of the kinetics of the polymerization reactions to those which we have obtained for the reactions of manganese carbonyl suggests that a preferable interpretation should include a substantial contribution from manganese-manganese bond fission.

We propose therefore that the initiation of polymerization could proceed by the reaction schemes A and B.

( $\{2\text{Mn}(\text{CO})_5\}$  represents two Mn(CO)<sub>5</sub> radicals trapped together in a solvent cage<sup>7</sup>.)

If we assume, with Bamford *et al.*<sup>1</sup>, that  $\cdot\text{CCl}_3$  is the only radical that initiates polymerization, and that it is 100 per cent efficient, then the rate,  $\omega$ , of reaction of vinyl monomer,  $M$ , by these two processes is given by

$$\omega = \omega_a + \omega_b = k_p k_t^{-1/2} [M] [\text{Mn}_2(\text{CO})_{10}]^{1/2} (a + b) \quad (i)$$

where  $k_p$  and  $k_t$  are the rate constants for propagation and termination of the chain reaction, respectively, and  $a$  and  $b$  are given by

$$a = \left\{ 1 + \frac{k_3[\text{CCl}_4]}{k_4 + k_3[\text{CCl}_4]} \right\}^{1/2} \left\{ \frac{k_1 k_2 [\text{CCl}_4]}{k_{-1} + k_2 [\text{CCl}_4]} \right\}^{1/2} \quad (ii)$$

$$b = \left\{ \frac{k_5 k_6 [\text{CCl}_4]}{k_{-5} [\text{CO}] + k_7 + k_6 [\text{CCl}_4]} \right\}^{1/2} \quad (iii)$$

This rate expression is in excellent agreement with all the data obtained by Bamford *et al.*<sup>1,2</sup>. Thus the rate of polymerization is first order in concentration of monomer, and half order in concentration of manganese carbonyl. At constant  $[\text{Mn}_2(\text{CO})_{10}]$ , the rate will increase with  $[\text{CCl}_4]$  and reach a limiting rate given by

$$\omega = (1.41 k_1^{1/2} + k_5^{1/2}) k_p k_t^{-1/2} [M] [\text{Mn}_2(\text{CO})_{10}]^{1/2} \quad (iv)$$

when  $k_3[\text{CCl}_4] \gg k_4$ ,  $k_2[\text{CCl}_4] \gg k_{-1}$ , and  $k_6[\text{CCl}_4] \gg k_7 + k_{-5}[\text{CO}]$ . At high values of  $[\text{CCl}_4]$  and constant  $[\text{Mn}_2(\text{CO})_{10}]$  the rate will decrease with increasing  $[\text{CO}]$ , and will reach a limiting rate given by

$$\omega = k_p k_t^{-1/2} [M] [\text{Mn}(\text{CO})_{10}]^{1/2} a \quad (v)$$

where  $a$  is equal to  $1.41 k_1^{1/2}$ .

This interpretation is in at least as good agreement with Bamford and Finch's data<sup>3</sup> as is theirs, which predicts a continuously decreasing rate with increasing  $[\text{CO}]$ . The fact that the variation of rate with  $[\text{CCl}_4]$  is of exactly the same form, whether carbon monoxide is present or not, is readily explained, because both  $a$  and  $b$  rise to limiting rates at high  $[\text{CCl}_4]$ , and the data are not sufficiently accurate at low  $[\text{CCl}_4]$  to distinguish between the more complicated behaviour expected in this region from the expressions for  $a$  and  $b$ , and that predicted by Bamford and Denyer<sup>2</sup>.

A quantitative comparison can also be made. Our values for  $k_1$  and  $k_5$  at 80°C in *n*-octane or decalin are  $1.0 \times 10^{-6} \text{ sec}^{-1}$  and  $0.33 \times 10^{-6} \text{ sec}^{-1}$  respectively. Solvent effects appear to be small, both for the substitution and oxidation reactions of manganese carbonyl<sup>8</sup> and for the polymerizations<sup>1</sup>. We calculate therefore that, at  $[\text{Mn}_2(\text{CO})_{10}] = 1.5 \times 10^{-3} \text{ mole l}^{-1}$ , and at high concentrations of carbon tetrachloride, the rate of polymerization is given by  $\omega = k_p k_t^{-1/2} (1.5 \times 10^{-3})^{1/2} (1.41 \times 10^{-3} + 0.57 \times 10^{-3}) [M]$ . For  $k_p k_t^{-1/2} = 0.14 \text{ mole}^{-1/2} \text{ l}^{1/2} \text{ sec}^{-1/2}$ , the gradient of a graph of rate of polymerization against  $[M]$  should be  $1.07 \times 10^{-5} \text{ mole l}^{-1} \text{ sec}^{-1}$ , as compared with the value of  $1.1 \times 10^{-5} \text{ mole l}^{-1} \text{ sec}^{-1}$  obtained by Bamford and Denyer<sup>2</sup>. The excellence of this agreement may well be fortuitous, however, because it is by no means certain that the "inactive products" in reactions (6) and (7) are indeed inactive.  $\text{Mn}_2(\text{CO})_9$  might well react, either with or without carbon tetrachloride, to give  $\text{Mn}(\text{CO})_5$  radicals which we believe to be, very probably, reactive species. Thus  $\text{Mn}(\text{CO})_5$  radicals are considered to react

Fig. 1. Variation of rate of polymerization of methyl methacrylate at 80° C with  $p(\text{CO})$ .  $[\text{Mn}_2(\text{CO})_{10}] = 2.37 \times 10^{-3}$  moles  $\text{l}^{-1}$ ,  $[\text{CCl}_4] = 0.191$  moles  $\text{l}^{-1}$ . Values given in ref. 1, Fig. 3;  $\times$ , values calculated according to reaction schemes A and B and our values of  $k_1$  and  $k_3$ . —, Curve calculated according to Bamford and Denyer's first mechanism<sup>1</sup>; ----, curve expected from our mechanism (exact degree of curvature is unknown).

very readily with bromine to form  $\text{Mn}(\text{CO})_5\text{Br}$  and  $\cdot\text{Br}$  in the chain reaction of bromine with manganese carbonyl<sup>8</sup>, and a similar reaction with carbon tetrachloride to form  $\text{Mn}(\text{CO})_5\text{Cl}$  and  $\cdot\text{CCl}_3$  seems highly likely. If either or both of reactions (6) or (7) produce an extra  $\text{CCl}_3$  radical in this way, then the calculated gradient would become  $1.20 \times 10^{-5}$  and  $1.31 \times 10^{-5}$  mole  $\text{l}^{-1}\text{sec}^{-1}$ , respectively.

For  $k_p k_t^{-1} = 0.22$  mole $^{-1}$   $\text{l}^{1/2}\text{sec}^{-1}$ , as used in reference 1, we calculate the rate in the absence of carbon monoxide, with high concentrations of carbon tetrachloride and with  $[\text{Mn}_2(\text{CO})_{10}] = 2.37 \times 10^{-3}$  mole  $\text{l}^{-1}$ , to be  $1.81 \times 10^{-4}$  mole  $\text{l}^{-1}\text{sec}^{-1}$ . The limiting rate in the presence of high  $[\text{CO}]$  is  $1.28 \times 10^{-4}$  mole  $\text{l}^{-1}\text{sec}^{-1}$ . These values are compared with the experimental data<sup>1</sup> in Fig. 1. Uncertainties of  $\pm 10$  per cent have been assigned to each point, as suggested by the mean deviation for  $k_p k_t^{-1}$ , calculated from the data (Table 1, ref. 1).

Bamford and Denyer<sup>2</sup> also measured the rate of evolution of carbon monoxide from solutions of manganese carbonyl, both in the presence and absence of carbon tetrachloride, and in the absence of oxygen. They assumed that, in the absence of carbon tetrachloride, the products were one mole each of  $\text{Mn}_2(\text{CO})_9$  and  $\text{CO}$  from each mole of  $\text{Mn}_2(\text{CO})_{10}$ . We have found no evidence for any such manganese carbonyl species in solution on examining the infra-red spectra of solutions of manganese carbonyl at 80° C, and have concluded that no inter-

mediate manganese carbonyl species is present in appreciable concentrations during the decomposition, that is, 10, not 1, moles of carbon monoxide are evolved for every mole of manganese carbonyl that reacts.

If only one mole is evolved, then the rate constant for decomposition becomes  $4.5 \times 10^{-6}$   $\text{sec}^{-1}$  at 80° C, as compared with our value<sup>7,8</sup> of  $1.33 \times 10^{-6}$   $\text{sec}^{-1}$  for the limiting rates of substitution by triphenylphosphine. On the other hand, if 10 moles are evolved the rate constant for decomposition is  $0.45 \times 10^{-6}$   $\text{sec}^{-1}$ . This is less than the rate of decomposition in the presence of oxygen because the reverse of reaction (1) is significant under these conditions<sup>7</sup>. In the presence of carbon tetrachloride, the rate of evolution of carbon monoxide from  $1.50 \times 10^{-3}$  molar manganese carbonyl is  $1.24 \times 10^{-5}$  mole  $\text{l}^{-1}\text{sec}^{-1}$ , but the nature of the products is uncertain.  $\text{Mn}(\text{CO})_5\text{Cl}$  must be formed<sup>9</sup>, and we find that this decomposes slowly at 80° C ( $t_{1/2} \geq 100$  min). Our value for the limiting rate

constant for the reaction of manganese carbonyl with species such as carbon tetrachloride, which attack both  $\text{Mn}_2(\text{CO})_9$  and  $\{2\text{Mn}(\text{CO})_5\}$ , is  $1.33 \times 10^{-6}$   $\text{sec}^{-1}$ . This means that the number of moles of carbon monoxide evolved from each mole of manganese carbonyl that reacts is  $1.24 \times 10^{-5} \div (1.33 \times 10^{-6} \times 1.50 \times 10^{-3}) = 6.3$ . This is quite consistent with the partial decomposition of relatively stable carbonyl species such as  $\text{Mn}_2(\text{CO})_8\text{Cl}_2$  (ref. 10) and  $\text{Mn}(\text{CO})_5\text{Cl}$  which are formed in the presence of carbon tetrachloride.

Finally it should be pointed out that, although the data for all these reactions of manganese carbonyl are fully consistent with a rate determining formation of a  $\{2\text{Mn}(\text{CO})_5\}$  radical pair, alternative formulations of this reactive intermediate are possible so that the activation energy of 37 kcal/mole may be only a lower limit for the manganese-manganese bond fission.

We thank the donors of the Petroleum Research Fund, administered by the American Chemical Society, and NATO, for support of this research.

Some divalent cation soaps are known to exhibit a body-centred cubic phase at high temperatures. X-ray crystallography now shows that the polar groups (cations and carbonyl groups) are arranged so as to form interwoven three-dimensional networks embedded in a continuous matrix formed by disordered paraffin chains.

ONE of the characteristics of the class of substances embodying soaps, detergents, phospholipids, sphingolipids—namely the lipids—is that it displays a variety of phases with a long range organization strictly periodic in one, two or three dimensions and yet with a highly disordered short range conformation. Such phases are

usually encountered with lipids and lipid-water systems when temperature and concentration are varied (for a review of the subject see refs. 1 and 2). A large number of phases of this type have been identified by X-ray scattering techniques and the structures of many of them have been determined<sup>1</sup>.

We describe here the body-centred cubic phase, first detected by one of us<sup>3</sup> in the strontium saturated soaps at about 230° C, in barium stearate above 220° C, and in calcium *p*-ethyl- $\omega$ -undecanoate at room temperature. The structure was solved by the application of crystallographic techniques more conventional than those used in previous studies of lipids. The structure displays some novel features: the polar groups are present on rods of finite length which belong to two interwoven infinite three-dimensional networks, and the hydrocarbon chains constitute a continuous paraffin matrix.

The experimental characterization of the body-centred cubic phase has already been described elsewhere<sup>3,4</sup>. Its chief properties can be summarized as: (a) it is optically isotropic; (b) in the "high-angle" region of the X-ray diffraction diagrams (namely for  $s = 2 \sin \theta / \lambda > (10 \text{ \AA})^{-1}$ ) only one diffuse band is observed, near  $s = (4.5 \text{ \AA})^{-1}$ , thus indicating that the conformation of the paraffin chains is highly disordered<sup>1,5</sup>; (c) a fairly large number of sharp reflexions are observed in the "small-angle" region (see Fig. 1 and Table 1), the position and intensity of which are almost independent of temperature; (d) the X-ray diffraction diagrams of the different soaps are remarkably similar—the ratios of the spacings as well as the relative intensity of the reflexions are identical (see Fig. 1).

Experimentally observed spacings and intensities, as obtained on Debye-Scherrer diagrams, are given in Table 1. These data, based on a recent careful inspection of the X-ray diagrams, involve a few minor corrections of the data presented earlier<sup>3,4</sup>. The lattice dimensions observed with various soaps are given in Table 2.

As has already been shown<sup>3,4</sup>, all the reflexions can be indexed on a body-centred cubic lattice (see Table 1). The cubic symmetry is confirmed by the optical properties; the lattice type appears to be defined unambiguously because neither a primitive nor a face-centred cubic lattice is compatible with the spacings of the reflexions.

Further developments in the structural analysis were guided by the following considerations: (a) only the

Fig. 1. X-ray diffraction diagrams of some strontium soaps, at 235° C. The camera is of the Guinier type, operating *in vacuo*, in symmetric position, with a sample-film distance of 125 mm. The radiation is the copper  $K\alpha$  line,  $\lambda = 1.54 \text{ \AA}$ . The sharp spots in the outer region are due to the mica windows of the sample holder. Note the similarity of the X-ray diagrams: the ratios of both the spacings and the intensities of the reflexions are the same for all the soaps. a, Myristate; b, palmitate; c, stearate; d, arachidate; e, behenate.

positions of the strontium ions are taken into account—the electron density is assumed to be uniform over the rest of the cell; (b) most of the absent reflexions can be explained by the space group symmetry—indeed the number of reciprocal lattice points with zero intensity is too large (see Table 1) to be ascribed to the form factor of the asymmetric unit; (c) it is probable that the structures of all soaps are related because they show similar X-ray diffraction patterns; (d) the locus of the strontium ions can be presumed to coincide with some symmetry element (that is, the strontium ions occupy special positions)—the shape of the structure elements is, in fact, likely to be defined by the symmetry of the cell, because the paraffinic regions, which constitute the bulk of the structure, lack internal rigidity<sup>1,6</sup>.

The most probable space group with absences to account for most of the observed absences without con-

$s_{\text{obs}}$  and  $s_{\text{cal}}$  are the reciprocal spacings ( $s = 2 \sin \theta / \lambda$ ) of the observed reflexions, and calculated for the body-centred cubic lattice with  $a = 63 \text{ \AA}$ .  $I_{\text{obs}}$  are the observed intensities, which were visually estimated (vvs, extremely strong; vs, very strong; s, strong; m, medium; w, weak; vw, very weak; vvw, extremely weak; see Fig. 1).  $F$  is the structure factor, calculated with the equation:

$$F_{h,k,l} = K \int_0^{0.1075} A_{h,k,l} \zeta(x, 1/4-x, 1/8) dx$$

where  $A_{h,k,l}$  is given in the *Intern. Tables* (ref. 7, pp. 524-525), and  $K$  is a normalization factor such that  $F_{0,0,0}$  is equal to the total length of the rods contained in one unit cell ( $F_{0,0,0} = 24 \times \sqrt{2} \times 2 \times 0.1075 \times a = 460 \text{ \AA}$ ). The reflexions forbidden by symmetry are indicated by *abs*.  $I_{\text{cal}}$  is the sum of  $(F_{h,k,l})^2$  for all the reciprocal lattice points with the same spacing, multiplied by the convergence factor  $\exp(-524 s^2)$ .

Table 2. SOME DATA RELEVANT TO THE STRONTIUM SOAPS AT 235° C

Soap	<i>a</i> (Å)	$\delta_{235^\circ \text{C}}$ (g cm <sup>-3</sup> )	<i>N</i>	<i>N</i> /24	<i>n</i> (Å <sup>-1</sup> )
Laurate	58.4	0.87 <sub>3</sub>	215	8.9 <sub>6</sub>	0.51 <sub>1</sub>
Myristate	62.6	0.85 <sub>4</sub>	233	9.7 <sub>1</sub>	0.51 <sub>5</sub>
Palmitate	66.2	0.84 <sub>9</sub>	245	10.3 <sub>4</sub>	0.50 <sub>5</sub>
Stearate	69.7	0.83 <sub>8</sub>	261	10.8 <sub>8</sub>	0.50 <sub>7</sub>

Behenate	76.0	0.82 <sub>6</sub>	285	11.8 <sub>8</sub>	0.50 <sub>4</sub>

*a* is the parameter of the body-centred cubic cell,  $\delta$  is the density of the soap, *N* is the number of soap molecules per cell, *N*/24 is the number of molecules per rod, *n* is the number of strontium ions per unit length of the rod.

The densities were first determined for the hexagonal phase, at 265° C, as discussed in the appendix of ref. 4, then corrected by the thermal factor  $\delta_{235} = \delta_{265}(1 + 0.000748 \times \Delta t) = \delta_{265} \times 1.022$ , taken from the data of the hexagonal phase of calcium stearate<sup>8</sup>. *n* is determined with the equation

$$n = (N/24) (0.250 \times \sqrt{2} \times a - 2 \times 1.56)^{-1}$$

assuming that the length of the segment devoid of strontium ions, near the ends of the rods, is 1.56 Å for all the soaps.

flicting with any of the observed reflexions (see Table 1) is *Ia3d* (No. 230 of the *International Tables*<sup>7</sup>). This space group possesses various sets of special positions. Those nominated *a*, *b*, *c*, *d* and *e* in the *International Tables* (ref. 7, pp. 345–346) are discarded, because they involve additional absences at variance with the experimental data. The position *f* (*x*, 0, 1/4, etc.) is also discarded because it involves  $F_{431} \equiv F_{543} \equiv 0$ , in contrast with the observed intensity of those reflexions (see Table 1).

Only one set of special positions is thus possible, nominated *g* in the *International Tables* (1/8, *x*, 1/4-*x*, etc.), which lies along two-fold axes. The structural factors of the various reflexions were calculated (see ref. 7, pp. 524–525) and the results were plotted as a function of *x*. It was noticed then that the agreement with the observed amplitudes is excellent if the structural factors are integrated over the interval  $0 < x < 0.1075$ , or, in other words, if the strontium ions are uniformly distributed over segments of the two-fold axis. The integrated structural factors and the intensity of the reflexions are given in Table 1: the calculations were carried out on a computer ('Univac 1107').

The convergence factor ( $\exp(-524s^2)$ ) (see Table 1) takes account of the actual electron density distribution in the cross-section of the rod, as well as of the disorder, due in particular to the fluctuations in the length of the rods (see below) and the thermal movements.

One projection of the unit cell, with some of the symmetry elements, is shown in Fig. 2*a* (the representation of all the symmetry elements would be confusing for such a high symmetry). The strontium ions are situated along rods of finite length, which lie along two-fold axes. Each end of a rod is grouped with two other rods, from which it is separated by a short gap (see below); the three rods of each group are coplanar, and are related by a three-fold axis perpendicular to the plane. The length of each rod is  $a \times 2 \times \sqrt{2} \times 0.1075$  (*a* is the cell parameter, see Table 2); twenty-four rods are contained in one unit cell. Neglecting the short gap, the rods define two infinite three-dimensional networks, mutually interwoven, and

otherwise unconnected. The structure is depicted in Fig. 2*b*.

The distribution of the strontium ions is uniform along the rods; the length of the gap from the end of the rod to the three-fold axis is (in myristate)  $a \times \sqrt{2} \times 0.0175 = 1.56 \text{ \AA}$ . The number of molecules per rod ( $N/24$ ) and the linear density (*n*) of the strontium ions along the rods are given in Table 2 and the values are based on the assumption that the length of the segments devoid of cations is the same for all soaps (the differences would be very small if the length were proportional to the lattice parameters). The number of cations per rod is not an integer and it may be presumed that it varies from rod to rod and from cell to cell, most likely within very narrow limits, and that  $N/24$  is an average over the whole crystal. The linear density of the cations is the same for all the soaps, at least within the scatter associated with the probable errors of  $\delta$  (see legend of Table 2).

The space between the rods is occupied by the paraffin chains, in a highly disordered conformation; these form a continuous matrix throughout the whole crystal. The distance from any point of the cell to one of the rods never exceeds the fully extended length of the chain; for example, the maximum distance is 11.1 Å in strontium myristate.

The diameter of the high electron density region, around the two-fold axes, is, of course, finite, and is negligible only in the most idealized model; it is clear that, taking into account the resolution of the data and the shape of the convergence function (see Table 1), the strontium ions may well be located at some distance from the two-fold axes, and thus leave room for the intercalation of the carboxyl groups. Furthermore the organization of the strontium ions, and probably of the carboxyl groups as well, appears to be quite ordered. Indeed, it may be noted that at higher temperature, in the phase that follows the cubic, the loci of the cations are rods of infinite length, parallel and organized on a two-dimensional hexagonal lattice<sup>3,4</sup>, the linear density of which is the same for all the strontium soaps ( $n = 0.496 \text{ cations/\AA}$ )

Fig. 2. Representation of the structure. The loci of the strontium ions, represented by heavy lines, are rods of finite length, that lie along two-fold axes. The ends of the rods are joined three-by-three. The gaps at the end of the rods are omitted. (a) Projection on the plane *ab*, with the position of some of the symmetry elements. The thin lines show the limits of one unit cell. The fractional figures are the *z* co-ordinates of the intersections of three rods. (b) Perspective view. The dotted lines are the projection of the heavy lines on the plane *ab*. Note the two three-dimensional networks mutually interwoven, otherwise unconnected.

and is almost identical to that of the cubic phase (Table 2). The organization of the polar regions thus appears to be quite similar in those two phases. This type of hexagonal phase has been observed in other divalent cation soaps, and the organization of the polar rods has been shown to be highly ordered, and this contrasts with the chaotic conformation of the paraffin chains<sup>3,4,8</sup>. A similar conclusion can thus be drawn for the hexagonal and the cubic phases of the strontium soaps.

The finite length of the rods of the cubic phase can be explained by the interplay of the ordered and the disordered regions. Indeed the separation of the paraffin chains along the rods is fixed by the organization of the polar groups. Under these conditions the average orientation of two neighbouring chains may not be quite random, if the flexibility is not sufficiently high. Assuming, more precisely, that the neighbouring chains tend to keep closer than is allowed by the separation of the polar groups, the structure becomes increasingly "strained" as the length of the rods increases. If the length of the rods is limited and the ends joined three by three, this releases the "strain" and preserves efficient space filling. It should be noted that a similar explanation, based on the interplay of the order of the polar groups and of the disorder of the paraffin chains, has been given for some of the phases exhibited by the sodium soaps<sup>9</sup>. It is to be expected that the polar groups at the junction of three rods will be organized in a different way from that of the rest of the rods, and thus the presence of the short segments of low electron density is not surprising.

If the clustering of the polar groups into rods of finite length, and the junction of the ends of the rods three by three, are justified, the precise three-dimensional structure can be visualized as a regular framework constructed with those elements. This class of structures has been discussed by Wells<sup>10</sup>; indeed the structure described here is one of those considered by him.

The similarity of the X-ray diffraction diagrams (see above) requires that the structure of all the soaps be related, that is, that the dimensions of the structure

elements be proportional to the cell parameter. This requirement would be strictly fulfilled if the length of the segments of low electron density, near the ends of the rods, were proportional to the cell parameter. In fact, the intensities calculated assuming that the length is constant are hardly different from those of Table 1, even in the case of behenate.

One final comment on the properties of other phases. All the phases described previously were supposed to be formed by structural elements the symmetry of which is analogous to that of the lattice: planar sheets for the one-dimensional (lamellar) lattice; circular cylinders for the two-dimensional hexagonal lattice; rectangular prisms for the two-dimensional rectangular lattice; spheres for the face-centred cubic lattice, etc. (see discussion in ref. 1). In many cases these hypotheses were confirmed by straightforward crystallographic analyses and by the analysis of some physical and chemical parameters. Nevertheless, for other phases it seems likely—especially as a consequence of the results described here—that some of the structures are in fact more complicated.

We thank Mme C. Saludjian for computing assistance. This work was supported in part by grants from the Délégation Générale à la Recherche Scientifique et Technique, Comité de Biologie Moléculaire, and from the Direction des Recherches et Moyens d'Essais, Ministère des Armées.

## Electrical Responses in Brain Samples

by  
C. D. RICHARDS  
H. McILWAIN

Department of Biochemistry,  
Institute of Psychiatry,  
De Crespigny Park,  
London, S.E.5

Small samples from the mammalian brain remain excitable *in vitro*, and spike discharges similar to many observed *in vivo* are evoked in neocortical samples. The autonomy of such samples will make them very valuable in investigations of the working of the brain.

STUDY of the mammalian brain *in situ* is conditioned and often limited by the complexity and interconnexion with other bodily events, which are characteristic of the brain as an organ. The innumerable interactions possible among the  $10^{10}$  neurones of the human brain have been often noted, and have prompted us to develop suitable means of examining quite small samples excised from the brain when investigating aspects of cerebral functioning. Application of these methods to the neocortex has hitherto given partial success, and it is this major part of the mammalian brain that presents the greatest problem in deciphering cellular interconnexions. We have now demonstrated in neocortical samples, weighing a few milligrams, several of the electrical and metabolic responses to applied stimuli previously recognized in the brain *in vivo*.

Tissue samples, about 0.3–0.4 mm in one dimension and a few mm in the others, were excised<sup>1</sup> and placed in an incubating solution at 38° C in a glass chamber<sup>2</sup>, within 1–2 min of exsanguinating a rat or guinea-pig. Neocortical tissues in these conditions in oxygenated solutions containing glucose have been found to maintain or to recover a variety of their *in vivo* attributes. These include their contents of energy-rich phosphates and sodium and potassium ions<sup>3</sup>, the resting membrane potentials of constituent cells<sup>2</sup> and several metabolic responses to excitation<sup>3</sup>. Thus although some damage is inevitable in excising the tissue sample (it has been quantitatively appraised<sup>4</sup> and concerns an area perhaps 0.1 per cent of the cell surfaces of the sample), the greater part is close to normal in many functional characteristics.

Electrical responses to stimulation were therefore sought. First, there were the results of stimulation for periods of some seconds or 1 min<sup>6</sup>. These were detected by micropipettes with a tip diameter of 0.5–1  $\mu$ , which were used intracellularly. Depolarization on stimulation and a slow subsequent repolarization were found.

Present experiments showed direct responses to individual stimuli, or to limited groups of stimuli, using glass micropipettes with tip diameter of 2–4  $\mu$ , filled with 20 per cent sodium chloride and used extracellularly. Conventional amplification and display techniques were used (see also Fig. 1). Stimuli were applied to the tissue through to two silver-silver chloride ball-tipped electrodes placed 1 mm apart on the upper surface of the tissue sample, while it was supported on a nylon grid at the surface of a glucose saline buffered by bicarbonate<sup>8</sup>. The stimulating electrodes were connected to two coupled 'Grass S4' stimulators through stimulus-isolation units.

Potential changes detected extracellularly (Fig. 1) were elicited in response to individual rectangular pulses of about 5 V and lasting 0.4 msec. Surface responses were positive, negative and negative-positive waves lasting about 10–20 msec, although in a few cases they lasted longer than 100 msec. These responses were detectable only within a 2 mm radius of the stimulating electrodes and the amplitude of the response fell rapidly as the recording electrode was moved away from the stimulating electrode, so that little was found at 2.5 mm. It is interesting that, much earlier, metabolic responses in neocortical samples to pulses similar to those now used were

Fig. 1. Potentials evoked in an isolated neocortical specimen in response to surface stimulation. *a*, A surface-positive wave, superimposed on a further response to a subsequent stimulus recorded 130  $\mu$  below the tissue surface. *b–d*, Responses recorded at one location, to identical surface stimuli delivered during 10 sec (in *b–d*, traces retouched). In this and in the other figures, arrows indicate stimuli and upward displacements represent positive potentials.

Fig. 2. Variation in evoked responses. The frames were taken at about 2 sec intervals while electrode placement and stimulus characteristics remained constant. The depth of the tip of the recording electrode was 180  $\mu$ .

found to be maximal with electrodes 1–2 mm apart<sup>7</sup>, and that a separation of 2 mm has been adopted in most subsequent metabolic measurements of response<sup>8,9,10</sup>.

Spike potentials have now been recorded at depths of 150–300  $\mu$  in response to surface stimulation (Figs. 1–3). These spikes could be classified into the first two of the three classes listed by Amassian<sup>9</sup>. They were either initially negative, both with and without a smaller positive phase following, or they were large positive-negative spikes. Monophasically positive spikes only occurred rarely as injury discharges. Most of the spikes encountered in penetrations of the cortex were of the initially negative variety. Their amplitude ranged from just above the noise level to about 1 mV and they lasted about 1 msec. These observations are very similar to observations of units recorded in grey matter *in vivo*<sup>9</sup>.

Examples of unit recording from *in vitro* neocortical preparations are shown in Figs. 1 and 2. Fig. 2 shows considerable variation in response to constant stimulus characteristics; possibly some degree of synaptic activation is the cause of this variability. Units in which activity had been evoked by surface stimulation were not susceptible to being driven at frequencies above about 20/sec, although precautions were taken to avoid electrode polarization.

The relationship between changes in the composition of the medium and the excitability of the slices has been examined. When most of the extracellular chloride ions were removed there was substantial increase in the excitability of guinea-pig hippocampus<sup>10</sup>. Similar experiments were attempted with neocortical samples. When sodium ethane sulphonate was substituted for sodium chloride, no seizure discharge was observed; but the surface cortical response increased in amplitude and

duration from 0.5 mV (peak amplitude) and about 20 msec (maximum duration) to 1.2 mV and 40 msec. There was no noticeable increase in the unit activity encountered. When lithium ion replaced sodium in the experiments it did not permit spike generation, but caused an irreversible loss of excitability, which occurred within 5 min of exposure to the lithium-saline.

Maintenance of function in isolation is familiar in excised samples from many parts of the mammalian body including muscle and peripheral nerve, but pessimistic statements have repeatedly appeared regarding tissues from the brain<sup>11,12</sup>. The present series of experiments provide a new outlook; they showed, first, the conduction of impulses along the lateral olfactory tract in small samples from the piriform lobe of the brain<sup>13,14</sup>, maintained *in vitro* with an experimental arrangement similar to that described previously, except that recording was extracellular and from the surface of the tissue sample. Complex responses were also found in the piriform cortex in such samples<sup>13-15</sup>, and in portions from the hippocampus of the brain of the guinea-pig<sup>10</sup>. The micropipette recording now applied to the neocortex also revealed unit activity in the piriform cortex in response to stimulation of the lateral olfactory tract<sup>14</sup>.

Each of these experimental systems offers special advantages and opportunities. Findings now reported with the neocortex have the merit of referring to the part of the brain which is most characteristic of higher animals, which has been most extensively studied by biochemical

techniques and which is available in the greatest quantity. The sample of piriform cortex which carries the lateral olfactory tract gives the best opportunity for examining the spread of the effects of stimulation, by normal routes of conduction and synaptic transmission. Metabolic studies<sup>13,17</sup> have suggested that the proportion of a 35 mg sample which was directly affected by localized stimuli was about 5 per cent, while up to 40 per cent of the tissue responded as a result of conduction and transmission. Thus this preparation showed the augmentation of response during a train of impulses, the alteration in amplitude during repetitive stimulation and the modified responses on high frequency stimulation<sup>13,14</sup>, which are also found *in vivo*<sup>18</sup>.

The piriform preparation has also proved interestingly susceptible *in vitro* to a number of centrally acting drugs<sup>13-15</sup>. Lack of suitable cerebral preparations has in the past partially caused the study of the action of several drugs the actions of which are primarily central (for example, anticonvulsants), to be carried out with preparations of peripheral nerve or ganglia, which are not their points of action as drugs *in vivo*. It is interesting that the hippocampal preparation, *in vitro*, exhibited seizure discharges in response to single stimuli when these were applied in media with a diminished chloride content<sup>10</sup>. The preparation has thus proved valuable in the understanding of central inhibitory phenomena by permitting much more facile control of ionic environment than is possible *in vivo*.

Fig. 3. Repetitive firing induced by surface stimulation in a sodium ethyl sulphonate medium. (a) Initial spike evoked by surface stimulation at the former cortical surface. After about 15-20 sec of continued stimulation at 1 pulse/sec, a second spike was seen (b); then, (c), high frequency discharges began after a further lapse of 20 sec. These discharges lasted about 20 sec (d-f), after which time only a few discharges were seen following stimulation. Calibrations: horizontal bars, 20 msec; vertical bars, 1 mV.

The samples which we have examined are about 1/50,000 of the size of the human brain, and when such samples are derived from the human brain itself, they have shown cellular potentials<sup>5</sup> and responses to stimulation<sup>19,20</sup>. The preparations clearly exhibit a newly recognized autonomy in the action of groups of cerebral cells, very relevant to the dictum "matter works itself" which was intriguingly discussed by Sherrington in relation to cerebral phenomena differently observed<sup>21</sup>.

## Neuronal Mechanisms of Habituation

by  
GABRIEL HORN

Department of Anatomy,  
University of Cambridge.

It is possible to account for many aspects of habituation without postulating an active gating process (such as proposed by Sokolov), but by supposing that the gradual waning of the response of a group of neurones to a repeated stimulus is caused by a self-generated depression of sensitivity at one or more places in the group.

An animal suddenly presented with a stimulus may respond by some movement of the body in which the sense organs are directed towards the source of the stimulus<sup>1</sup>. At the same time certain vegetative changes occur, including an alteration in blood pressure and heart rate as well as changes in the electroencephalogram. Repeated presentation of the stimulus at intervals of about a second or more brings about a gradual waning of this orientation response which can, however, be provoked again if the original stimulus is applied after a prolonged interval of time<sup>2-5</sup>. I shall use the term "habituation" to describe these phenomena—the attenuation of response associated with repeated presentation of stimulus and the recovery of response which may afterwards be induced.

Many of the characteristics of habituation can be observed in single neurones. Studies of such cells in invertebrates<sup>6-8</sup> and vertebrates<sup>9-14</sup> have shown that the response to an infrequently presented stimulus decays after a few presentations, although neurones in close synaptic connexion with receptors do not appear to exhibit this behaviour<sup>15</sup>. In vertebrates, the phenomenon does not depend on the integrity of the "higher centres", because it can be observed in cells of the mid-brain after the removal of the neo-cortex<sup>16</sup> and in cells of the spinal cord separated from the brain<sup>13,14,14a</sup>.

In addition to response decrement, these neurones show many of the properties which characterize other aspects of habituation. The recovery of response to the original stimulus usually occurs provided the stimulus is withdrawn for a sufficient length of time before being presented again<sup>8,10,12,17</sup>. In cells which can be driven by different stimuli, for example, acoustic and photic stimuli, Horn and Rowell (in preparation) and others<sup>8,10,12</sup> found that failure of response to one of them may be without influence on the ability of the other to elicit a response.

A view that has gained considerable currency, and which attempts to account for habituation of the orientation response, is that proposed by Sokolov<sup>18</sup>. In this theory an afferent signal is conveyed to the sensory cortex and also, through axon collaterals, to the reticular formation. Access of the signal to the reticular formation is controlled by fibres originating in the cortex. The cortex stores a neuronal representation of stimuli which have been presented in the past. If this representation

matches the incoming signal, impulses descend from the cortex and prevent the signals in the afferent collaterals from activating the reticular formation. If the stimulus is a novel one, it will have no neuronal representation and the descending discharge from the cortex facilitates the passage of signals from the axon collaterals to the reticular formation. Thus response decrement to a repeatedly applied stimulus is the result of an active gating process controlled by the output of a matching system.

As a general theory of habituation, this model is unsatisfactory. For one thing, response decrement can occur in the absence of the cerebral cortex. Then elaborate neuronal circuitry is invoked to account for certain phenomena which could be accounted for more economically. An environment matching system similar to that proposed by Sokolov is probably essential for some but not for all properties of habituation.

The object of this article is to consider what aspects of habituation can be accounted for on the hypothesis that the gradual waning of response of a system of neurones to a stimulus which is slowly and repeatedly applied is a result of a self-generated depression of sensitivity (SGD) at one or more points in the system. This hypothesis differs from that of Sokolov<sup>18</sup> which supposes that response decrement is caused by an active blocking of transmission, the gate being operated by the output from a matching system. The term self-generated depression of sensitivity is used in the present context as a generic term to include such phenomena as after hyperpolarization, conduction block due to accumulation of potassium ions in the extracellular clefts surrounding an active fibre, synaptic depression which probably represents an imbalance between the mobilization and utilization of transmitter and, in certain circumstances, recurrent inhibition and prolonged primary afferent depolarization as found in the spinal cord and thought to be partly responsible for presynaptic inhibition.

### Response Decrement and Recovery

Let us suppose that a neurone ceases to respond to a repeated stimulus but responds vigorously to another stimulus applied to a sense organ of a different modality;

Fig. 1. A spot moved from left to right in the visual field activates a group of cells whose discharge reaches the recorded cell *R* over pathway *AR*. When the spot is moved from right to left a different group of cells is activated and this discharge reaches cell *R* over pathway *BR*.

and that when the original stimulus is withdrawn for some time and then presented again, the cell responds once more. This behaviour would be expected if there were an SGD in the pathway transmitting the signal evoked by the repeated stimulus. Thus if the response of the cell to a tone presented once every 4 sec had waned as a result of such a depression somewhere in the pathway linking the cell to the basilar membrane, a photic stimulus would still be able to drive the recorded cell provided the acoustic and photic stimuli did not evoke activity in anatomically overlapping pathways to the cell. The ability of the original stimulus to elicit a response after a period of withdrawal would depend on the rate at which the SGD recovered.

Thus the whole sequence of events—gradual failure of response, recovery after a lapse of time and the potency of an additional stimulus—could be accounted for by SGD assuming that the activity evoked by the repeated and additional stimuli reached the recorded cell over anatomically independent pathways. It is clear<sup>19-22</sup> that specific features of a stimulus often trigger specific groups of neurones. To take an example, a spot of light moved across the visual field in the horizontal meridian will activate a specific group of cells in the rabbit retina<sup>21</sup>; if the direction of movement of the spot is now reversed, activity will be evoked in another group of cells. If both groups are connected to a cell (for example, cell *R* in Fig. 1) by independent pathways, then a spot moved in either direction will drive it. Should there be an SGD as a result of stimulus repetition in the pathway linking one group of directionally selective cells to the recorded cell (for example, SGD between cells *B* and *R* in Fig. 1), cell *R* will cease to respond to that stimulus. If, however, the spot of light is moved in the reverse direction and so activates the other group of directionally selective cells, *R* will discharge. Thus cell *R* is unresponsive to the repeated stimulus but can be activated if one of the parameters of that stimulus is changed.

A set of experimental results which is difficult to account for in this way is that in which an additional stimulus, which differs from the repeated stimulus only in being less intense, evokes a response<sup>5,12</sup>. Voronin and Sokolov<sup>5</sup> used this difficulty as one of the crucial arguments for their active gating theory. The less intense stimulus might be expected to use a pathway to the

recorded cell coincident with or contained within that used by the original stimulus; if the response of the recorded cell waned because of SGD in that pathway, a less intense stimulus must also fail to activate the cell. Such a conclusion is inevitable if the assumption about common pathways is correct. Is it?

Goldberg and Greenwood<sup>23</sup> recently showed that about a quarter of the neurones in the dorsal cochlear nucleus of the cat which were examined in detail showed a non-linear increase in firing rate as the intensity of a tone stimulus was increased. In fact, as the intensity increased the firing rate of such a unit increased, reached a peak and then decreased. Units which respond in a similar way to photic stimuli have been described in the cat retina<sup>24</sup>. Consider an array of five such neurones, the firing rate of each of which is plotted against stimulus intensity (Fig. 2*A*). At the intensity corresponding to arrow 2, cell *D* fires maximally and the other cells fire relatively slowly. At the intensity corresponding to arrow 1, cell *B* discharges maximally and the others weakly or not at all. The output from such an assembly of neurones will transmit the intensity parameter of the stimulus along specific neurones. This assembly of neurones is shown in Fig. 2*B*. The more intense stimulus evokes activity in the recorded cell *R* over the pathway from cell *D*, and the less intense stimulus over a different pathway from cell *B*. If the response of the recorded cell to the more

Fig. 2. *A*, Intensity/response curves of five (theoretical) neurones with properties similar to the non-linear units of Goldberg and Greenwood<sup>23</sup>. The number of spikes (ordinate) is plotted against stimulus intensity (abscissa). Arrows below the co-ordinate legends indicate direction of increasing magnitude. *B*, The neurones *A*, *B*, ..., *E* whose intensity/response curves are plotted in 2*A* are connected by separate pathways to recorded cell *R*. The response of cell *R* to an iterated stimulus which evokes activity over pathway *DR* gradually wanes as a result of self-generated depression of sensitivity at the synaptic junction indicated by the arrow.

Fig. 3. Synaptic depression at the terminals of cell *A* may temporarily be restored through the activity of the inhibitory neurone (indicated by the broken line) from the reticular activating system.

intense stimulus wanes as a result of an SGD at the junction indicated by the arrow in Fig. 2*B*, the ability of the less intense stimulus to drive cell *R* will remain unaffected.

### Dishabituation

A transitory recovery of the orientation response to the repeated stimulus may occur after the presentation of an additional stimulus<sup>3,18,25-27</sup>. The effect is known as dishabituation. The additional stimulus may be a sudden loud sound, a bright flash of light or a shock applied to the skin. Horn and Rowell (in preparation) observed a similar effect which occasionally occurs in single nerve cells<sup>10</sup>. How this effect is brought about will depend on the mechanism of response waning, that is, on the basis of the SGD. Such depression may be brought about in a number of ways, but for the purposes of the following discussion it is assumed that it represents an imbalance between the processes of transmitter mobilization and utilization similar to that seen at neuromuscular<sup>28-30</sup> and synaptic<sup>31,32</sup> junctions. There is indeed some direct evidence that synaptic depression is the basis of a response failure to slowly repeated stimuli in *Aplysia*<sup>17</sup>. (If the SGD were the result of some other process—for example, accumulation of potassium ions in the spaces surrounding the fine axon terminals—dishabituation might be brought about in ways similar to, but not identical with, those described later in this article.)

We can account for dishabituation in the following way (see Fig. 3—in this and all figures continuous lines indicate excitatory connexions and broken lines indicate inhibitory connexions). A painful or intense stimulus activates in mammals<sup>33</sup> the widely connected system of fibres<sup>34</sup> known as the reticular system. If, for example, neurones of this (non-specific) system hyperpolarize the terminals of cell *A* on cell *F* the effect might be to increase the amount of available transmitter substance<sup>32,35,36</sup>. Thus once the response of cell *F* to the repeated stimulus has failed as a result of synaptic depression an additional, intense stimulus might activate the non-specific system and so lead to hyperpolarization of the terminals of cell *A* on *F*. If the original stimulus is now applied, the discharge it evokes in cell *A* will lead to a larger excursion of the membrane potential at the synaptic terminals of *A* on *F*, more transmitter will be liberated and cell *F* will fire. In this way the additional stimulus has temporarily made the repeated stimulus potent. A sudden increase in the activity of the non-specific system, unprovoked by a sensory stimulus, might have the same effect; so that occasionally there would be a spontaneous recovery to the iterated stimulus, an effect which has been described in single cells and in the intact organism. A similar recovery would be achieved if the non-specific system, activated by the additional stimulus, depolarized and hence facilitated cell *F*. The previously sub-threshold

amount of transmitter substance liberated at the terminals of cell *A* in response to the iterated stimulus would now become threshold to the facilitated cell *F* which would fire. It is thus of considerable interest that Comis and Whitfield<sup>37</sup> have shown that acetylcholine applied locally to neurones in the cochlear nucleus of the cat increases their sensitivity to auditory stimuli; and that the non-specific system connecting with this nucleus is cholinergic<sup>38</sup>.

### Stimulus Generalization

An interesting feature of habituation may be illustrated by the following experiment<sup>12</sup>. While recording from a cell in the optic tectum of rabbit a tone of 1,000 c/s was delivered and evoked a response from the cell; so also did a tone of 950 c/s of similar intensity. The 1,000 c/s tone was repeatedly presented until the cell no longer responded to it. One of the 1,000 c/s tone pips was then omitted from the sequence of presentations and the 950 c/s tone substituted. This stimulus now failed to evoke a discharge. Such a broadening of the response decrement to include stimuli other than the repeated stimulus is known as stimulus generalization, and the two stimuli are then said to be equivalent. To account for stimulus equivalence, consider Fig. 4. The cells marked *R*<sub>1</sub> correspond to cell *R* in previous figures, that is, on repeatedly presenting a stimulus their response gradually wanes. Cells *P* and *Q* are each considered to require activity in three or more *R*<sub>1</sub> cells in order to be discharged. A 1,000 c/s tone is repeatedly presented and cells *R*<sub>1</sub> . . . *R*<sub>4</sub> gradually cease to discharge; so do cells *P* and *R*<sub>1</sub>. The 950 c/s tone is now presented. It may be seen that this tone reaches cell *Q* through cells *R*<sub>3</sub> . . . *R*<sub>6</sub>. Cells *R*<sub>3</sub> and *R*<sub>4</sub> will not discharge, nor will cell *Q*, because it is not excited by the minimum number of inputs. Cell *R*<sub>1</sub> will not therefore respond to the 950 c/s tone and the two tones are said to be equivalent. Stimulus equivalence on this model is a consequence of channel overlap.

### Time Dependent Effects

There is one set of results that certainly cannot be accounted for by the SGD/channel-dependent code hypothesis alone. Sokolov<sup>18</sup> found that after extinction of the orientation response to a regularly repeated stimulus a "response" appeared when one of the stimuli in the sequence was omitted. He also found that if one of the iterated stimuli was lengthened a response appeared at the time the repeated stimulus would have ended; and if the duration of the stimulus was reduced, the response appeared when this briefer stimulus ended. Sokolov<sup>39</sup> has also described single cells in the hippocampus the response of which to a repeated stimulus gradually wanes, but which gives a discharge when one of the stimuli of the sequence is omitted. This effect may be a specialized

Fig. 4. See text for discussion.

property of certain neuronal assemblies, because it has not yet been reported to occur elsewhere than in the hippocampus.

In order to account for these time dependent effects (of omitting a stimulus from a sequence or of changing the duration of one of the stimuli) it seems essential to introduce a system that detects the difference between past and present activity<sup>18</sup>. The way in which a difference detecting system might operate may be considered with reference to Fig. 5A. Suppose that cells *A* and *K* are simultaneously active and each discharge *N* spikes for *t* sec. Cell *J* will be depolarized by the *N* spikes in *K* and hyperpolarized by *N* spikes from *A*. Thus the excitatory and inhibitory inputs exactly balance (assuming linear transmission) and cell *J* is silent. For similar reasons cell *H* is silent. Because cell *G* is not excited by *J* or *H*, it also is silent. If in another circumstance cell *K* discharges  $N + \Delta N$  spikes and cell *A* discharges *N* spikes, cell *H* will be silent. This is because it is excited by *N* spikes from cell *A* and inhibited by  $N + \Delta N$  spikes from *K*. Cell *J*, however, will fire because it is excited by  $N + \Delta N$  spikes from *K* and inhibited by *N* spikes from *A*. Because *J* discharges  $\Delta N$  spikes, so also will cell *G*. Thus cell *G* discharges the number of spikes equal to the difference between the spike discharges in fibres *A* and *K*.

The difference detecting circuit is incorporated into the neuronal assembly illustrated in Fig. 5B, which contains cell *R*, the response of which gradually wanes if a stimulus

is repeatedly presented. This cell also shows the various time-dependent properties implied by Sokolov's<sup>18</sup> results. Suppose that cell *A* maintains its response to a repeated stimulus and that the waning of response of cell *R* is due to an SGD localized in the terminals of cell *A* on *F*. At no other point in the circuit does this depression occur. Within this circuit, cell *K* is considered to possess certain special properties. These are: (i) if a stimulus is repeatedly presented and then withdrawn cell *K* will discharge at the time the next stimulus would have appeared<sup>40</sup> and the discharge contains the same number of spikes and lasts the same length of time as the discharge evoked by the actual stimulus; (ii) if after this period of "training" by stimulus repetition some parameter of the stimulus is suddenly changed, the discharge elicited in cell *K* corresponds to that evoked by the iterated stimulus<sup>41</sup>. Thus if the iterated stimulus generates *N* spikes for *t* sec in cell *A* it will also evoke the same number of spikes for the same length of time in cell *K*. If the stimulus is now shortened and evokes a spike discharge in *A* for less than *t* sec cell *K* will nevertheless discharge *N* spikes over *t* sec. That is, cell *K* has a memory of certain aspects of the repeated stimulus which is released by activity in fibre *A*. ("Cell *K*" may, of course, be an assembly of cells which collectively possess the properties ascribed to this cell.)

When a novel stimulus is first applied to cell *A*, cell *R* is excited over the pathway *A**F**R*; cell *G* is silent because the discharge in cell *K* is equal to that of fibre *A* (linear transmission at the *A*/*K* synaptic junction). The stimulus is now repeatedly presented and, after the response of *R* has waned, one stimulus of the series is omitted. Cell *K* will discharge at this time and cell *J* will also discharge because it receives no inhibitory input from fibre *A*, which is silent. Cell *G* will discharge *N* spikes for *t* sec, so also will cell *R*, which thus appears to "respond" to the omitted stimulus.

If the duration of one of the iterated stimuli is suddenly changed, cell *G* will fire for the difference between this new duration and the duration, *t* sec, of the iterated stimulus, and so will cells *F* and *R*. Thus the neuronal circuitry illustrated in Fig. 5B will confer on cell *R* all the properties of habituation that have already been described, including the time dependent properties (it is assumed that a stimulus which differs from the iterated stimulus in some way other than duration will reach cell *R* over a different pathway from that illustrated in the circuit). It would, of course, be necessary to introduce time delays between cells *A* and *F*, but this might be done quite easily by having a chain of neurones interposed between the two cells. (It is worth noting that if the duration of the stimulus were transmitted by a channel-dependent code, as proposed for intensity, the only result that could not be accounted for by the SGD/channel-dependent code hypothesis is that in which a response occurs when a stimulus is omitted.)

Most of the properties of short term habituation can be accounted for by the neuronal systems that have already been described. In all these systems it is assumed that recovery of response to the repeated stimulus after a lapse of time is due to restoration of the SGD. Now there is some evidence that the response of a cell to a repeated stimulus may be depressed for several hours<sup>8</sup>. In behaviour, this depression may last for as much as 24 h or even longer<sup>27,42-44</sup>. Whether such long term effects rule out any possibility of accounting for response recovery after a lapse of time in terms of a spontaneous very slow restoration of the SGD can only be decided by a further analysis of habituation and of the properties of synaptic junctions in the central nervous system.

In the meantime, we should bear in mind the possibility that several mechanisms may be used in the central nervous system to bring about the set of phenomena that have been termed habituation.

I thank Professors A. S. V. Burgen, J. S. Griffith and R. A. Hinde and Dr P. R. Lewis for helpful dis-

## Histochemistry of the Mucosaccharides in the Epiphyseal Plate of Young Rabbits

by

MARGARET WILLIAMSON  
JANET VAUGHAN

MRC Bone-Seeking Isotopes Research Unit,  
Churchill Hospital,  
Oxford

Histochemical observations on sections of the epiphyseal cartilage plate of young rabbit bones suggest that free anionic sites are present in the hypertrophic cartilage zone. This finding may help to explain why this cartilage zone takes up certain radionuclides and may throw light on the mechanisms involved in the initiation of calcifications.

IMMEDIATELY after an intravenous injection of americium and plutonium, these radionuclides become concentrated in a narrow band in the zone of hypertrophic cartilage cells at the base of the epiphyseal plate<sup>1</sup> (Fig. 1). To understand why they become concentrated here, it seemed of interest to study the histochemistry of this anatomical site in frozen undecalcified sections and to compare it with the histochemistry of the same site in sections fixed in the usual ways. This comparison appeared essential for at least two reasons. First, it is known that certain mucosubstances capable of binding cations<sup>2</sup> are soluble in the solutions used in ordinary histological procedures<sup>3-6</sup>; and second, the difficulties in identifying histochemically components rich in carbohydrate must be recognized<sup>7</sup>. Tissues of a single age only were investigated because the histochemical properties of young rat epiphysis change markedly with age<sup>8</sup>.

Blocks from the distal end of the femur of rabbits 10 days old were frozen in liquid nitrogen immediately after removal at autopsy. Sections were cut on a Cambridge rocking microtome in a Pearce cryostat at a temperature between  $-18^{\circ}$  and  $-20^{\circ}$  C. Coverslips at room temperature were used to lift the  $5\mu$  sections off the knife. Sections were dried and stored at room temperature. Subsequently they were stained: (i) without further treatment; (ii) after they had been fixed with Lillie's formalin-acetic acid-alcohol (FAA)<sup>9</sup> for 5 min; (iii) after

Fig. 1. Autoradiograph left on longitudinal section of epiphyseal plate from the femur of a young dog killed 4 h after an injection of  $5\mu\text{Ci}$  of  $^{241}\text{AmCl}_3$ . Note band of  $\alpha$  tracks over hypertrophic cartilage cells.

decalcification with the disodium salt of ethylenediamine tetraacetic acid (EDTA)<sup>10</sup> at pH 7 for 5 min; or (iv) after fixation followed by decalcification. For comparison, paraffin sections were cut from blocks which have been fixed in either a neutral (Lillie's neutral formalin<sup>9</sup>, NF) or an acid medium (FAA) before decalcification in aqueous EDTA at neutral pH. The blocks were washed in running water for 3 h after both fixation and decalcification.

Two types of histochemical technique were used. First, those dependent on the affinity of tissue anionic groups for cationic dyes, namely, toluidine blue (pH 4) or azure A, aldehyde fuchsin, high iron diamine, and 'Alcian Blue' (at pH 1.0 and 2.5; and at pH 5.6 dissolved in magnesium chloride solutions of various molarities). Details of theory and procedure are summarized elsewhere<sup>11,12</sup>. Second, another dependent on the condensation with salicylhydrazide of the aldehydes engendered by the periodate oxidation of the vicinal glycols of the carbohydrate fraction of mucosubstances. The products thus formed from sialomucins emit a particularly intense blue fluorescence after being treated with a solution of an aluminium salt<sup>12</sup>.

The results of using the cationic dyes are shown in Table 1. Toluidine blue, aldehyde fuchsin and high iron diamine stain the whole plate in all sections, however prepared, but the colour is more intense over the hypertrophic cartilage cells in the frozen undecalcified sections. Toluidine blue does not stain the cartilage remnants before decalcification.

'Alcian Blue' at pH 2.5 imparts to frozen untreated sections a deep stain in the matrix and cells of the lowest hypertrophic layer and in the longitudinal bars which survive as the cores of the metaphyseal trabeculae. The rest of the plate is extremely pale (Fig. 2A). After sections have been fixed with FAA there is a slight extension upwards in the direction of the epiphysis of the deep staining reaction (Fig. 2B). In decalcified frozen sections (Fig. 2C) and in paraffin sections the whole plate is deeply stained.

In frozen fixed sections stained first with high iron diamine and then with 'Alcian Blue' at pH 2.5, only the granules in the hypertrophic cells take up 'Alcian Blue'. This is not seen in decalcified or paraffin sections.

Table 1. STAINING DISTRIBUTION IN FROZEN AND PARAFFIN SECTIONS

	Frozen	Frozen FAA	Frozen EDTA	Paraffin NF
<b>'Alcian Blue' pH 2.5</b>				
Hypertrophic matrix	4	4 } Extending	4	4
Hypertrophic cells	3	3 } slightly	3	3
Rest of plate	1	1	4	4
Calcified remnants	4	4	4	4
<b>Aldehyde fuchsin</b>				
Hypertrophic matrix	4	4	4	4
Hypertrophic cells	3	3	3	3
Rest of plate	3	3	3	4
Calcified remnants	4	4	4	4
<b>High iron diamine</b>				
Hypertrophic matrix	4	4	4	4
Hypertrophic cells	1	1	1	1
Rest of plate	3	4	4	4
Calcified remnants	4	4	4	4
<b>Toluidine blue pH 4</b>				
Hypertrophic matrix	M	M	M	M-B
Hypertrophic cells	M	M	M	M
Rest of plate	M	M	M	M
Calcified remnants	B*	B*	M	M

Intensity of staining estimated on scale 4 (very strong) to 1 (weak).  
M, Metachromasia; B, orthochromasia.

\* Occasional metachromasia which is only pale if present.

Table 2. EFFECT OF pH ON 'ALCIAN BLUE' STAINING OF UNTREATED, CRYOSTAT AND ROUTINE PARAFFIN SECTIONS

	Untreated cryostat	NF/EDTA paraffin	FAA/EDTA paraffin
<b>'Alcian Blue' 1 per cent; 30 min</b>			
<b>pH 1.1</b>			
Hypertrophic matrix	4	4	2
Hypertrophic cells	4-3	4	1
Rest of plate	3-2	4	2
Calcified remnants	4	4	2
<b>pH 2.5</b>			
Hypertrophic matrix	4	4	2
Hypertrophic cells	3	4-3	1
Rest of plate	1	4	1-0
Calcified remnants	4	4	2
<b>pH 5.6</b>			
Hypertrophic matrix	4	3	3
Hypertrophic cells	3-2	2	3
Rest of plate	3	3-2	2
Calcified remnants	4	3	3

Intensity of staining estimated on scale 4 (very strong) to 1 (weak).

The effect of pH on 'Alcian Blue' staining is shown in Table 2. In general, the degree of staining of untreated frozen and NF-fixed paraffin sections is comparable and is always more intense than in paraffin sections fixed in FAA. Likewise, increasing the pH of azure A solutions

Fig. 2. Longitudinal sections of femoral epiphyseal plate from young rabbit stained with 'Alcian Blue' pH 2.5 ( $\times 60$ ). A, Frozen untreated showing heavy staining of hypertrophic cell zone; B, frozen fixed (FAA) showing extension of heavy staining towards the epiphysis; C, frozen decalcified (EDTA) showing heavy staining of whole plate.

Table 3. ALCIANOPHILIA AT pH 5.6 IN THE PRESENCE OF MAGNESIUM CHLORIDE

	Molar magnesium chloride									
	0	0.05	0.1	0.2	0.3	0.4	0.6	0.8	1.0

Calcified remnants	2	3	3-2	2	2-1	2-1	±	0	0	

Intensity of staining estimated on scale 4 (very strong) to 1 (weak).

favours increased metachromasia of the matrix. Table 3 summarizes the effect of different molarities of magnesium chloride on the uptake of 'Alcian Blue' at pH 5.6. In the absence of magnesium ions the matrix of the entire plate stains heavily; the positive reaction of granules in the cytoplasm of the hypertrophic cells is also marked. The latter is reduced in the presence of 0.2 molar magnesium chloride, whereas the reaction of the matrix is not markedly reduced until 0.6 molar magnesium chloride is reached. It is eliminated in the presence of 0.8 molar magnesium chloride. As is indicated in Table 2, staining decreases more rapidly in the interterritorial matrix than in the matrix immediately around the cell as the molarity of the magnesium chloride increases.

The periodic acid-salicylhydrazide-aluminium procedure induces some fluorescence over the region of the hypertrophic cells. The fluorescence is reduced in sections incubated beforehand in neuraminidase.

The results obtained in this study, though in detail confusing, suggest that there are more free anionic sites in the zone of hypertrophic cartilage cells than elsewhere. The uniform staining throughout the plate in paraffin sections and in frozen decalcified sections indicates that the decalcifying and embedding processes liberate anionic sites which then bind cationic dyes to the same degree and in all sites. Such preparations give no opportunity to discriminate between different mucosubstances. Three of the cationic dyes used, toluidine blue (or azure A), aldehyde fuchsin and high iron diamine, give the same result in both frozen and paraffin sections except that in the frozen sections the zone of hypertrophic cartilage cells is more deeply stained. Their reaction is not affected by pH. 'Alcian Blue' stains the whole plate in frozen sections only at a higher pH and is considered later.

The fact that aldehyde fuchsin stains the whole plate in frozen sections while 'Alcian Blue' does not, except at a high pH, needs an explanation. Perhaps the acid in the aldehyde fuchsin solution strips cations originally present on the anionic groups or mucosubstances. If it does, the anionic sulphate sites thus exposed would take up aldehyde fuchsin in the normal way. Alternatively, aldehyde fuchsin may have a greater inherent affinity for mucin sulphate groups than the metal cations or even hydrogen ions originally bound to them. The cations are possibly peptides or calcium ions. The latter, though they do not show up with the usual histochemical methods for calcified deposits<sup>11</sup>, are present in the rabbit tissues studied here, as shown by micro-incineration (0.4 per cent calcium dry weight). Hjertquist<sup>13</sup> found 1.5 per cent calcium on a dry weight basis in the non-calcified epiphyseal plate in the dog as compared with 10 per cent in the zone of provisional calcification.

Aldehyde fuchsin, high iron diamine and, to a lesser extent, toluidine blue stain sulphated mucopolysaccharides specifically and the results with these dyes substantiate what is already known from chemical analyses<sup>14</sup>, namely, that there are large amounts of sulphated mucosubstances throughout the plate. The fact that in frozen undecalcified sections the cells of the hypertrophic zone are more deeply

stained by these dyes suggests that there is a greater concentration of free ester sulphate groups here than in the rest of the plate. On the other hand, it has been shown chemically that there is no change in sulphur concentration in different regions of the plate<sup>14</sup> and this has been confirmed by autoradiographic studies<sup>15</sup> using <sup>35</sup>SO<sub>4</sub>.

The ester sulphate groups in the hypertrophic zone may have fewer metabolic cations or, as seems more likely, amino-acids or proteins bound to them than those elsewhere in the plate. Thus more of them would be free to take up basic dyes in the histochemical experiments. This is borne out by the experience of others. Amprino<sup>16</sup> shows that the basophilia of undecalcified bone increased following trypsin digestion, and Szirmai, Van Boven de Tyssensk and Gardell<sup>17</sup> have described amino-acids blocking the basophilic groups of nasal septum cartilage. Dziwiakowski and his group<sup>15,18</sup> have also provided immunological and autoradiographic evidence that some protein is removed from the zone of provisional calcification but not from elsewhere.

The results with 'Alcian Blue' are, however, much more informative. In frozen undecalcified sections 'Alcian Blue' at pH 2.5 stains only the region of the hypertrophic cartilage cells at all darkly, thus suggesting that free anionic sites capable of binding this dye are present in this site alone. Frozen sections fixed in FAA are stained in a slightly wider zone (Fig. 2B) presumably because more anionic sites have been liberated, but it was only after decalcification that the whole plate stains at this pH (Fig. 2C). Further, when sections are stained with high iron diamine followed by 'Alcian Blue' at pH 2.5 the cells, as distinct from the matrix, of the hypertrophic zone are stained by 'Alcian Blue'. In this sequence this is considered to indicate the presence of non-sulphated mucosubstances, that is, sialomucins and hyaluronic acid<sup>11,12,19</sup>. This observation alone suggests that in the hypertrophic region the cells themselves contain probably a sialomucin or hyaluronic acid. These mucins may also be present in the matrix of these cells, but their presence here is masked by the far deeper staining of the more highly concentrated chondroitin sulphate. The results obtained with 'Alcian Blue'-magnesium chloride solutions confirm this suggestion<sup>20</sup>. In this laboratory Herring has found that the alcianophilia of an isolated bone sialoprotein and a bone chondroitin sulphate fraction on cellulose acetate strips is inhibited by 0.2 molar magnesium chloride and 0.6 molar magnesium chloride, respectively. In the case of the frozen sections the 'Alcian Blue' staining of the intracellular granules in the hypertrophic cells was greatly reduced at 0.2 molar magnesium chloride, suggesting the presence of a sialoprotein, while at 0.6 molar magnesium chloride the staining of the rest of the plate is less strong and except for the outer zone of the articular cartilage extinguished at 0.8 molar magnesium chloride.

The positive fluorescence obtained with the salicylhydrazide technique substantiates the presence of a sialomucin in the hypertrophic zone. The finding that the fluorescence is reduced by previous treatment with neuraminidase, however, must be treated with caution. The use of enzymes to remove selected compounds should in theory provide good specificity, but in practice there are many difficulties, among them the impurities of many enzyme preparations and the fact that in the process of incubation itself important compounds may be extracted apart from the specific enzyme action<sup>21</sup>.

This histochemical identification of a sialoprotein in the hypertrophic cells is confirmed by some biochemical evidence<sup>22</sup>. Jibril and Lindenbaum<sup>22</sup> have demonstrated, with sodium hydroxide extraction, an appreciable excess of extractable sialic acid in the zone of calcification of the calf scapula compared with the resting zone, 0.7 per cent of dry weight compared with 0.2 per cent. They suggest that this is normally bound to a chondromucoprotein. In 1964 Hjertquist found a slightly higher concentration of

hyaluronic acid in the zone of provisional calcification than elsewhere in the plates. Hirschman and Dziewiatkowski<sup>18</sup> have demonstrated a removal of protein, probably by proteolytic action, from the protein-polysaccharide complexes in this zone which may indeed explain the present observation that there are here free anionic groups capable of binding 'Alcian Blue' and therefore other cations. The finding of a sialoprotein, which in the case of the bone sialoprotein isolated by Herring<sup>4,5</sup> is known to be capable of binding certain cations even more strongly than it does calcium ions, in this zone is of interest<sup>2</sup>. The presence of these free anionic sites in the zone of hypertrophic cartilage cells may explain the initiation of calcification here and the ability to concentrate cations like americium and plutonium.

Thus the appropriate uses of 'Alcian Blue' and the periodic acid-salicylhydrazide-aluminium technique on frozen undecalcified sections of the epiphyseal cartilage plate of young rabbit bones suggest that mucosubstances with anionic sites are present in the hypertrophic cartilage zone and that they are free to bind the dye and therefore possibly other cations. This observation may explain both the initiation of calcification and the uptake of plutonium and americium at this site.

We thank Dr Peter Stoward and Dr Geoffrey Herring for helpful discussions, and Mr John Halfacree for technical help.

The 'Alcian Blue' dye (8GX 300) was a gift from Imperial Chemical Industries, Ltd.

Boston, and Harvard Medical School

Understanding of the renin-angiotensin humoral system has been held up for lack of a really specific and quantitative method of measuring angiotensin in plasma. A very sensitive radioimmunoassay for the hormone, which can be used on small samples of human plasma, has been developed.

We have demonstrated that antibody to angiotensin can be elicited in rabbits by copolymers of the hormone with poly-L-lysine. The octapeptide can be attached by its carboxy-terminal phenylalanine to the  $\epsilon$ -amino groups of the lysine residues by a carbodiimide condensation or coupled by its amino-terminal asparagine either with *m*-xylylene diisocyanate<sup>1</sup>, or by a carbodiimide condensation with succinyl poly-L-lysine<sup>2</sup>. Bovine serum albumin has also been used as a macromolecular carrier for angiotensin<sup>3</sup>. Poly-L-lysine as a carrier offers the advantages of low intrinsic immunogenicity and its  $\epsilon$ -amino group permits specific orientation of the molecule of angiotensin.

Asp(NH<sub>2</sub>)<sup>1</sup>-Val<sup>5</sup>-angiotensin II ('Hypertensin', given by Ciba) is used as the reference standard in the assay, and also as the isotopically labelled tracer after iodination with iodine-125 (ref. 4). After iodination antiserum added in excess is used to select the labelled angiotensin with the greatest affinity for the antibody. It is then liberated from antibody at pH 2 (ref. 1). The labelled material separated by gel filtration has a specific activity of approximately 220,000 c.p.m./ $\mu$ g, and moves as a single peak on high voltage electrophoresis.

The separation of antibody-bound and free angiotensin was achieved by gel filtration<sup>1,5</sup>. Another method of separation has been developed since then, utilizing half-saturated ammonium sulphate to precipitate antibody-bound hormone together with a carrier amount of rabbit gamma-globulin. This method gives results identical to those obtained by gel filtration and permits analysis of a larger number of samples.

Fig. 1 shows a typical standard curve in which displacement by increasing amounts of unlabelled angiotensin II is expressed in the percentage of the initial bound to free ratio ( $B/F$ ). Self displacement achieved by increasing amounts of the labelled hormone follows the same curve indicating that labelled and unlabelled angiotensin have the same reactivity toward the antibody. The association constant ( $K_A$ ) is  $2 \times 10^9$  l./mole. The usual dilution of the antiserum is 1:2,000, giving a sensitivity of 0.05  $\mu$ g for each assay.

The high specificity of this immunoassay is demonstrated by the fact that large excesses of bradykinin and vasopressin, and of peptide mixtures obtained by enzyme hydrolysis of lysozyme, do not displace labelled angioten-

sin from antibody. The binding activities of various analogues and enzyme fragments of angiotensin itself are shown in Table 1. Compound 2 has the sequence of bovine angiotensin II, while compound 3 has been found in horse and hog, and has been reported as the probable sequence in man<sup>6</sup>. These compounds have identical binding properties to compound 1 employed in the synthesis of the immunogen. Angiotensin I (compound 4) and compounds 5-9 obtained by enzyme hydrolysis of compound 1 display diminished affinity for the antibody.

Table 1. RELATIVE BINDING AFFINITY OF VARIOUS ANALOGUES, PRECURSORS AND ENZYME FRAGMENTS OF ANGIOTENSIN II, AS MEASURED BY RADIO-IMMUNOASSAY

Compound No.	Amino-acid sequence	Binding activity
1	H-Asp (NH <sub>2</sub> )-Arg-Val-Tyr-Val-His-Pro-Phe-OH	1
2	Asp-Arg-Val-Tyr-Val-His-Pro-Phe-OH	1
3	Asp-Arg-Val-Tyr-Ileu-His-Pro-Phe-OH	1
4	H-Asp (NH <sub>2</sub> )-Arg-Val-Tyr-Val-His-Pro-Phe-His-Leu-OH	1/20
5	H-Asp (NH <sub>2</sub> )-Arg-Val-Tyr-Val-His-Pro-OH	1/170
6	H-Val-Tyr-Val-His-Pro-Phe-OH	1/2
7	H-Asp (NH <sub>2</sub> )-Arg-OH	1/1,760
8	H-Asp (NH <sub>2</sub> )-Arg-Val-Tyr-OH	1/4,600
9	H-Val-His-Pro-Phe-OH	1/18,700

In our procedure the plasma is adjusted to pH 5.5 and diisopropylfluorophosphate and 'Dowex 50W-X2' in ammonium cycle are added. Duplicate 2 ml. samples of plasma are used for measurement of angiotensin and for renin activity. The first duplicates are kept on ice, while the latter are incubated for 3 h at 37° C with constant agitation. All are then transferred into small columns which are washed with 0.2 molar ammonium acetate, pH 6.0, followed by water. The sample is then eluted with 0.1 molar diethylamine, then 0.2 molar ammonium hydroxide, and the eluate is brought to pH 5.5 with glacial acetic acid. The samples are evaporated to dryness, resuspended and re-evaporated three times from 80 per cent ethanol. Finally, the samples are redissolved in 0.1 molar tris-buffer (pH 7.5) with 1 mg/ml. of lysozyme added to prevent adsorption of angiotensin on glassware, and the labelled hormone and antiserum are added. The mixtures are equilibrated for 18 h at 4° C, after which the bound and free hormone are separated and counted in a well-scintillation detector.

Reproducibility in individual samples is  $\pm 5$  per cent. Recovery of added angiotensin from plasma as compared with recovery from buffer subjected to the procedure described here is 90 per cent to 110 per cent. The concentration of angiotensin in plasma is calculated from

Fig. 1. Radioimmunoassay of angiotensin; displacement obtained with increments of unlabelled angiotensin II (●) and with increments of labelled angiotensin II (○) expressed as a percentage of the initial bound to free ratio (B/F).

Fig. 2. Radioimmunoassay of angiotensin; comparison of the displacement of labelled angiotensin from antibody achieved by stepwise dilutions of material extracted from human plasma with the displacement achieved by increments of unlabelled synthetic angiotensin II. ○, Synthetic angiotensin II; ●, stepwise dilution of human angiotensin.

the observed ratio of bound to free hormone by comparison with the curve relating ratio to standard solutions of angiotensin. The displacement of labelled hormone by human angiotensin extracted from a plasma with high renin activity is identical with that of synthetic material (Fig. 2). Similar results are obtained when purified human renin (Haas preparation) is added to plasma before incubation.

As in other radioimmunoassays, the values found in human plasma are much lower than the ones obtained by bioassay. Table 2 gives the values found in normals and in certain disease states. These preliminary observations suggest that the method could have wide applicability in studying the role of the renin angiotensin system in man. Its chief advantages are its extreme sensitivity and high specificity, allowing the measurement of circulating concentrations of angiotensin and of renin activity, independently of other vaso-active substances, in small plasma samples.

The fate of labelled free fatty acids in isolated perfused livers shows that on entering the liver they are esterified or oxidized. The more acid which enters the oxidation pathway, the more goes into ketogenesis and the less into the citric acid cycle, so that the total production of energy remains constant.

The free fatty acids of the plasma (or non-esterified long chain fatty acids) arise primarily from the hydrolysis of triglyceride in adipose tissue<sup>1</sup>. Their concentration is increased during starvation and other conditions associated with ketosis. Free fatty acids labelled with carbon-14 are taken up by the liver, where either they are esterified into triglycerides or phospholipids and secreted ultimately by the liver as lipoproteins<sup>2</sup>, or they are catabolized by  $\beta$ -oxidation to carbon dioxide or ketone bodies<sup>3,4</sup>. Fatty acids, however, in the form of chylomicron triglyceride are not metabolized to any appreciable extent by the isolated perfused liver<sup>4</sup>. There is good evidence therefore for free fatty acids being the principal substrate for the production of ketone bodies by the liver. These relationships are summarized in Fig. 1.

It is evident that the pathways in the liver (Fig. 1) leading, first, to the esterification of incoming free fatty acids and, second, to the production of carbon dioxide through the citric acid cycle, could act competitively to the pathway leading to ketogenesis and they may be regarded therefore as potentially antiketogenic. Fritz<sup>5</sup> suggested that an increased capacity of the liver to esterify free fatty acids diverts some of the influx from the oxidative pathway leading to ketogenesis. Glycerol was later shown to be antiketogenic with respect to oleic acid, which is esterified readily, but not with respect to caprylic acid, which is not esterified readily<sup>6</sup>. Exton and Edson<sup>7</sup> have demonstrated that the antiketogenic effect of sorbitol or fructose on the oxidation of <sup>14</sup>C-palmitate by liver slices is accounted for, partly, by incorporation of label into esterified fatty acids. We considered that a study of

the factors affecting the fate of free fatty acids in the isolated intact organ perfused with whole blood would give information reflecting more accurately the mechanism of hepatic ketogenesis and antiketogenesis *in vivo*. An isotopic balance was drawn up between the esterification of labelled free fatty acids on the one hand, and their oxidation on the other, in livers from fed or fasted animals perfused with three different concentrations of free fatty acids.

The perfusion apparatus and method of perfusion of the liver have been described elsewhere<sup>8</sup>. Livers from male rats (weighing 340–360 g) were perfused with whole defibrinated rat blood, care being taken to exclude heparin from both the liver donors and the perfusate to avoid the activation of lipoprotein lipase<sup>4,9</sup>, which catalyses the hydrolysis of lipoprotein triglycerides to free fatty acids. Livers were infused for 90 min with either 150 mg, 50 mg or a trace amount of oleic acid-1-<sup>14</sup>C complexed to bovine serum albumin. The infusion was given for the first 5 min as a priming dose followed by an infusion at one-tenth the rate of the priming dose for the remaining 85 min. The purpose of the priming infusion was to establish as rapidly as possible a steady concentration of labelled free fatty acids in the perfusate. During the course of the perfusion serial analyses were carried out for respiratory <sup>14</sup>CO<sub>2</sub> (ref. 8) and for <sup>14</sup>C-ketone bodies in blood<sup>10</sup>. Serum lipoproteins were separated into  $d < 1.006$  (very low density lipoproteins or VLDLP) and  $d > 1.006$  fractions by ultracentrifugation. <sup>14</sup>C-lipids were separated into classes by silicic acid chromatography and counted as described before<sup>2</sup>.

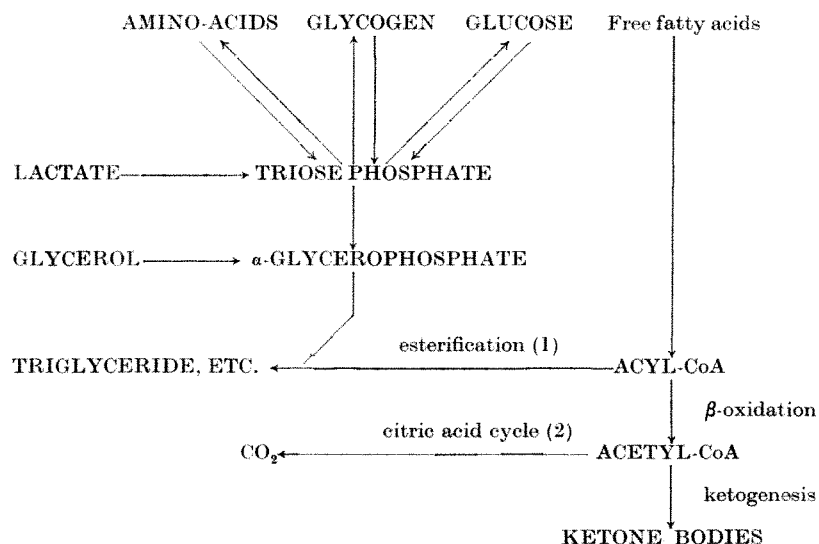

Fig. 1.

Table 1. FATE OF INFUSED FREE FATTY ACIDS (<sup>14</sup>C-OLEATE) IN PERFUSED LIVERS

Nutritional state of liver	Fed			Fasted (24 h)		
	Trace (2)	50 mg (1)	150 mg (2)	Trace (2)	50 mg (1)	150 mg (2)

Oxidized products						
In carbon dioxide	2.4 (1.9-2.9)	5.7	6.2 (5.0-7.3)	18.4 (12.4-24.4)	14.5	4.3 (3.3-5.2)
In total ketone bodies	0.8 (0.0-1.6)	4.6	4.2 (3.3-5.0)	5.0 (3.3-6.7)	18.3	19.9 (19.9-19.9)
Total	3.2	10.3	10.4	23.4	32.8	24.2
Total carbon-14 esterified and oxidized	74.5	54.8	44.1	50.7	54.7	44.1
Labelled free fatty acids remaining in perfusate	19.9 (14.5-25.4)	15.7	18.7 (17.5-20.0)	22.1 (22.0-22.2)	27.2	21.0 (20.2-21.8)
Total carbon-14 recovered	94.4	70.5	62.8	72.8	81.9	65.1

Table shows percentages of infused labelled oleate recovered in 90 min.

The number of perfusions and experimental variation between duplicate perfusions is shown in parentheses.

The fate of labelled free fatty acids infused into isolated perfused rat livers is summarized in Table 1. Those labelled acids remaining in the perfusate after 90 min of perfusion were slightly less than 20 per cent of the total dose infused in the fed livers and slightly more than 20 per cent in the fasted livers. In these perfusions, the concentration of serum free fatty acids in the steady state established by the infusion ranged from 0.2 to 1.5  $\mu$ moles/ml. depending on the mass infused. There was a constant rate of blood flow in all perfusions and so these results show that in both fed and fasted livers there is a constant fractional uptake of free fatty acids by the perfused liver for most of the range of concentrations of free fatty acids in the plasma encountered *in vivo*. For any given infusion of labelled free fatty acids the fed livers always esterified more of the influx than the fasted livers and the latter always oxidized more than the former. In the livers infused with 50 mg or 150 mg of <sup>14</sup>C-oleic acid, the total carbon-14 found in esterified plus oxidized products of metabolism was similar in livers from fed and fasted rats for each quantity of free fatty acids infused. The balance of the label not esterified in the fasting livers compared with the fed livers was completely accounted for by the extra label recovered in oxidized products, particularly in ketone bodies. Clearly, there is a reciprocal relationship in the liver between the esterification of incoming free fatty acids and their oxidation.

In livers from fed rats the proportion of the free fatty acids esterified was inversely related to the mass of the acids infused (Table 1). A different pattern of esterification was found in fasted livers. Not only was less of the influx esterified but, in contrast, the fraction of the labelled fatty acid esterified was constant irrespective of the mass of fatty acids infused. It has been generally considered that the availability or concentration of  $\alpha$ -glycerophosphate in a tissue is a primary factor influencing the rate of esterification of fatty acids<sup>5,6,11</sup>. This concept, however, has been challenged in respect of muscle<sup>12</sup> and adipose tissue<sup>13</sup>. Nevertheless, with respect to the liver Bortz and Lynen<sup>14</sup> have produced direct evidence that the concentration of  $\alpha$ -glycerophosphate in livers from fasting rats is depressed compared with the concentration in livers from fed animals, and Wieland and Matschinsky<sup>6</sup> have shown that the addition of carbohydrate (fructose) to the perfusate of isolated livers increases the concentration of  $\alpha$ -glycerophosphate in the tissue.  $\alpha$ -Glycerophosphate is derived in part from intermediates of glycolysis, and so it is probable that in the present experiments the high content of glycogen in the livers of fed rats ensured a high concentration of  $\alpha$ -glycerophosphate, which in turn could account for the greater and characteristic pattern of esterification reported in these livers. While the lower rate of esterification found in the livers from fasted rats can be attributed to a decreased concentration of  $\alpha$ -glycerophosphate, however, the pattern of esterification, showing that a constant fraction (about 20 per cent) of the free fatty acids utilized was esterified, irrespective of its mass, is difficult to explain solely in terms of a low concentration of  $\alpha$ -glycerophosphate. It must be concluded that there are sufficient

precursors of  $\alpha$ -glycerophosphate to maintain this small but constant fractional esterification, even in the face of a large influx of free fatty acids.

A greater proportion of the labelled oleic acid taken up by the liver was returned to the perfusate as lipoproteins in the livers from fed rats than from fasted rats. Most of the label secreted in lipoproteins was found in the very low density fraction (*d* < 1.006) in confirmation of previous results using intact rabbits<sup>2</sup>. As the influx of free fatty acids into the liver increased, so the mass of labelled fatty acid oxidized increased in both fed and fasting livers. The proportion of label entering ketone bodies compared with the proportion entering carbon dioxide also increased, particularly in livers from fasting rats.

For the administration of the radioisotope in the experiments described, the "constant infusion" procedure (as against the "single dose" procedure) was employed to minimize effects on the results caused by variations in the size of intermediary pools and to allow time for equilibration of label in side pools of the main pathways. The substantial total recovery of label (Table 1) indicates that these factors would not significantly affect the general conclusions concerning these data. To eliminate misinterpretation, however, we have examined preparations that were in a completely isotopic steady state. This necessitated taking biopsies from the liver.

In two perfusions, one with a liver from a fed rat and the other from a fasting rat, 150 mg of labelled oleic acid was infused for 90 min as described previously. Within 30 min constant specific activity of the serum free fatty acids was achieved. Samples were taken, including biopsies, after 60 min and after 90 min and analysed for labelled products of the metabolism of labelled free fatty acids. The radioactivity which accumulated in all the measured products in 60-90 min could be equated completely with the radioactivity of the oleic acid removed from the perfusate during this time (Table 2), indicating that all pathways of quantitative importance in the metabolism of free fatty acids by the liver were being measured. While the data in Table 1 indicate the relative importance of the various pathways being exam-

Table 2. FATE OF INFUSED FREE FATTY ACIDS (<sup>14</sup>C-OLEATE) IN PERFUSED LIVERS

Nutritional state of liver	Fed	Fasted

Percentage of <sup>14</sup>C-oleate utilized between 60 and 90 min appearing in metabolic products (150 mg infused in 90 min).

ined, the data in Table 2 indicate the quantitative significance of the pathways, because they are being assayed in a system in complete isotopic equilibrium. These data show that at least 50 per cent of the influx of free fatty acids into the liver, even in the fasting state, is esterified. This fraction approaches 80 per cent in the fed preparation. The reciprocal relationship between esterification on the one hand, and oxidation on the other, confirms the data in Table 1. The partition of the labelled molecules between oxidation to carbon dioxide and oxidation to ketone bodies indicates that oxidation of fatty acid through the citric acid cycle becomes less as ketogenesis increases. These results agree with those of Wieland *et al.*<sup>15</sup>, who observed an inhibition of the oxidation of <sup>14</sup>C-acetate to labelled carbon dioxide in liver slices from ketotic rats, but are at variance with the results of Ontko<sup>16</sup>, who found that oxidation of labelled palmitate to labelled carbon dioxide in liver homogenates was not diminished, but increased asymptotically as the concentration of fatty acid in the medium was increased.

In the six perfusions reported in Table 3, we have calculated and compared the energy yield, as adenosine triphosphate (ATP) resulting from the utilization by the liver of 1 mole of oleic acid. Although the fasting livers oxidized nearly twice as much of the labelled oleic acid as the fed livers, both obtained approximately the same energy from each mole of free fatty acid utilized, because of oxidation of fatty acid through the citric acid cycle which yielded more energy than partial oxidation to ketone bodies. Thus it seems that when the liver is presented with a quantity of fatty acid for oxidation, the molecules are so distributed between the efficient pathway (the citric cycle) and the inefficient pathway of oxidation (ketogenesis), that the total energy yield from the fatty acid remains constant. Apparently the liver is enabled to oxidize an almost unlimited quantity of fatty acid, without increasing its energy production, merely by diverting more of the oxidation from the production of carbon dioxide to ketogenesis. The limit in the quantity of fatty acids that could be oxidized by the liver would be reached theoretically when all molecules were being oxidized to ketone bodies and especially to  $\beta$ -hydroxybutyrate. Further oxidation of fatty acid could only take place by increasing the oxidative requirements of the liver or by means of a mechanism similar to the uncoupling of oxidation and phosphorylation. It has been suggested that a way in which the liver is enabled to change from the oxidation of fatty acids through the citric acid cycle, to ketogenesis, may involve the inhibition of citrate synthase by an increase in the steady state concentration of intramitochondrial ATP<sup>17</sup>.

Studies subsequent to those reported have shown that the oxidation of the infused labelled free fatty acids (Table 2) accounts for approximately two-thirds of the total oxygen consumption of either the fed or starved perfused liver. A respiratory quotient of 0.99 for fed perfused livers (not infused with fatty acids) suggests

that these livers oxidize largely carbohydrate<sup>18</sup>. Present results indicate therefore that when free fatty acids are infused into the fed liver in the conditions described, they displace much of the available carbohydrate as the chief fuel of respiration. This conclusion is similar to that of Randle *et al.*<sup>19</sup>, who observed that free fatty acids depress glucose utilization in rat heart and diaphragm. The oxygen consumption of perfused livers from fed and fasted rats is similar<sup>18</sup> and we have found that it remains essentially the same when a concentration of free fatty acids comparable to that used in the present experiments is infused. It seems probable that in the present conditions, oxidation and phosphorylation in the liver remain tightly coupled when free fatty acids are infused. Because the fasting livers produce substantially more ketone bodies than the fed livers, our results do not support the hypothesis<sup>20</sup> that uncoupling of oxidation and phosphorylation by free fatty acid is a cause of ketogenesis.

Results from this and previous studies<sup>21</sup> suggest that ketogenesis is controlled by metabolism in both adipose tissue and the liver. The primary factor appears to be the magnitude of the flux of free fatty acids entering the liver which is determined by the rate of release of the acids from adipose tissue. The principal hepatic factor responsible for antiketogenesis is the capacity of the liver to esterify incoming fatty acids, which in turn is related to the availability of carbohydrate, the esterifying capacity of livers from fed animals containing appreciable quantities of glycogen, being superior to those from fasted animals containing no glycogen. The degree of ketogenesis is determined subsequently by the magnitude of the flux of fatty acids which escape esterification. The acetyl-CoA formed in  $\beta$ -oxidation of fatty acids can enter either into the high energy yielding, non-ketogenic pathway of oxidation to carbon dioxide, or two molecules can condense to enter the low energy yielding, ketogenic pathway. The factor which determines the relative rates of each pathway appears to be the total energy requirement of the liver. Thus as more fatty acids flood the pathway of  $\beta$ -oxidation, more enter the pathway of ketogenesis and less enter the citric acid cycle, controlled in such a manner that the total yield of energy from oxidation remains constant.

Table 3. ENERGY DERIVED FROM OXIDATION OF FREE FATTY ACIDS (LABELLED <sup>14</sup>C-OLEATE) IN PERFUSED LIVERS UNDER STEADY STATE CONDITIONS

	Percentage of <sup>14</sup> C utilized			Fasting livers		
	(a)	(b)	(c)	(d)	(e)	(f)
In respiratory carbon dioxide	12.4	12.7	11.8	6.6	6.9	6.2
In total ketone bodies	8.4	6.6	10.7	38.6	30.8	21.7
$\beta$ -Hydroxybutyrate	6.5	4.7	4.2	34.2	7.7	5.0
Acetoacetate	1.9	1.9	6.5	4.4	23.1	16.7
Energy yield (calculated)						
(Moles of ATP/mole of oleate utilized)						
Through CO <sub>2</sub> pathway (citric acid cycle)	17.7	18.1	16.9	9.4	9.9	8.9
Through ketone body pathway	2.1	1.7	3.2	8.9	9.8	7.0
Total	19.8	19.8	20.1	18.3	19.7	15.9

Oleic acid was infused at the rate of 150 mg in 90 min. In experiments a, b, and d, the PO<sub>2</sub> of the blood entering the liver was 70 mm mercury. In experiments c, e, and f, the PO<sub>2</sub> was 95 mm mercury. The calculations are based on the <sup>14</sup>C-oleate utilized over a period of 30 min in the steady state. The percentage of the label appearing in respiratory CO<sub>2</sub> and in total ketone bodies has been corrected for decarboxylation of acetoacetate.

## ASTRONOMY

## Large Scale Density Inhomogeneities in the Universe

Sachs and Wolfe have recently considered the possibility of large scale density inhomogeneities in the universe with characteristic dimensions of the order of  $10^8$  parsecs.<sup>1</sup> The suggestion<sup>2</sup> that quasi-stellar sources with highly red-shifted spectra are not isotropically distributed has aroused interest in large inhomogeneities. Rees and Sciama<sup>3</sup> have suggested that the tendency to cluster of quasi-stellar sources with large  $z$  implies that the mass of the universe may not be homogeneously distributed on a scale of  $z \sim 1$ . Although the observational status of the anisotropy of the distribution of these sources is in some doubt<sup>4</sup>, we have recently obtained results which appear to set rather stringent limits on the magnitude of possible density inhomogeneities in the universe.

The recently discovered cosmic microwave background<sup>5-8</sup> originates at an epoch corresponding to a very large red-shift, and thus provides a powerful tool for investigating the isotropy and homogeneity of the universe on the largest scale. We have already pointed out<sup>9</sup> that our early results set limits of the order of 10 per cent to the large scale density inhomogeneities of the type considered in ref. 1. Conklin and Bracewell<sup>10</sup> have shown that inhomogeneities greater than 0.2 per cent in the background radiation do not appear to be present on a scale of angular resolution of the order of  $1^\circ$ , at least in the restricted area of the sky they surveyed.

For the past fifteen months, we have measured the isotropy and homogeneity of the cosmic microwave background. A Dicke radiometer operating at 3.2 cm wavelength was specially designed for this experiment<sup>9</sup>. Our measurements were made by comparing the temperature of the background microwave radiation along a full circle running  $8^\circ$  south of the celestial equator with the temperature measured at the north celestial pole, a fixed point in the sky. The temperature difference is displayed as a function of right ascension in Fig. 1, in which each point represents an average of the data obtained from about eighty runs, each of which lasted about 24 h. Before the results were averaged, a constant instrumental offset,  $C_{24}$ , was subtracted from the data of each run (see ref. 9). The temperature difference was averaged over an hour

Fig. 1. Changes in the temperature of the background radiation along a circle parallel to the celestial equator at  $-8^\circ$  dec. are displayed. The measurements were made with a 3.2 cm radiometer having an angular resolution of about 1 h in right ascension.

in sidereal time because this is approximately the angular resolution of our horn antenna. It can be seen from Fig. 1 that the largest departure from zero is of the order of  $0.016^\circ$  K, which should be compared with  $3^\circ$  K, the assumed value for the mean temperature of the microwave background<sup>6-8</sup>. Most of the random error in the data arises from fluctuations in the radiation temperature of the atmosphere; we estimate that this random error is about  $\pm 0.003^\circ$  K.

The passage of the central region of the Milky Way through our beam may be indicated by the slight increase in  $T_E$  at 19 h R.A. At  $\sim 2$  h R.A. and near the celestial equator, there appears to be a more extended region of lower temperature. This feature closely corresponds in position and extent to one of the clusters of quasi-stellar sources suggested by Rees and Sciama<sup>3</sup>. Because the depth of this feature is only a few times the estimated error for a single point, however, its existence cannot yet be regarded as well established.

This research was supported in part by the US Office of Naval Research and by the US National Science Foundation.

## PLANETARY SCIENCE

## Luni-Solar Daily Variations of the Geomagnetic Field at Tananarive during the International Geophysical Year

A PROGRAMME for the analysis of IGY data from magnetic observatories for luni-solar variations has recently been extended to the observatory at Tananarive, Madagascar ( $18^\circ 55' \text{ S}$ ,  $47^\circ 33' \text{ E}$ ). This site is of particular interest because it lies at dip latitude  $\varphi = -34.8^\circ$  ( $\tan \varphi = \frac{1}{2} \tan I$ , where  $I$  is the magnetic dip). No data between  $\varphi = -24^\circ$  (St. Helena,  $D$  only) and  $\varphi = -47^\circ$  (Cape Town, Hermanus) have previously been analysed. In addition Tananarive is an inland observatory, so it is unlikely to have an anomalous luni-solar variation in  $Z$ , as is the case for coastal observatories<sup>1</sup>.

The data consisted of instantaneous values of  $D$ ,  $H$  and  $Z$  measured every 2 h at odd hours of Universal Time from July 1, 1957–December 30, 1958. Because of breaks in the records, August 22 and 23, 1958, were omitted for all elements and August 13 and 14, 1958, for  $D$ . Also, for reasons considered earlier<sup>1</sup>, the five International Disturbed Days of each month were omitted.

The method of analysis and derivation of vector probable errors followed that described by Leaton, Malin and Finch<sup>2</sup>, which is closely similar to that of Chapman and Miller<sup>3</sup>. The object of the analysis was the calculation of  $l_n$  and  $\lambda_n$ , the amplitude and phase of  $L_n$ , the luni-solar daily harmonic

$$L_n = l_n \sin(nt - 2v + \lambda_n)$$

where  $n$  is a small integer,  $t$  is the mean solar time measured from local midnight and  $v$  is a measure of the epoch in a lunation which increases from 0 at one new moon to  $2\pi$  at the next.

Each element was analysed as a whole ( $Y$ ) and also as subdivided into Lloyd's seasons: November, December, January and February ( $W$ ); March, April, September and October ( $E$ ); May, June, July and August ( $S$ ). It should be noted that, in the southern hemisphere,  $S$  corresponds to winter and  $W$  to summer months. The results are presented in Table 1.

As usual, the  $L_2$  terms are by far the most important, and most of the determinations of  $l_2$  are significantly different from zero at the 5 per cent level. There are also a number of significant determinations of  $l_1$  and  $l_3$ , including a large value of  $l_3$  for  $D$  ( $W$ ).

$p.e.$ , Vector probable error.

Harmonic dials of  $L_2$  are shown in Fig. 1 for Tananarive (filled circles) and for the British Isles (open circles). The British Isles values are means deduced from analyses of IGY data at Eskdalemuir, Hartland, Lerwick and Valentia<sup>1</sup>, and are included for comparison. The dial vectors are indicated only by their end points.

The distribution of the seasonal values of  $L_2$  ( $D$ ) about the mean is closely similar to that obtained in the British Isles, although the range of nearly  $5\gamma$  from summer to winter at Tananarive is much greater.  $L_2$  ( $H$ ) also shows a similar pattern to that obtained for the British Isles,

Fig. 1. Harmonic dials of  $L_2$  for Tananarive (●) and the British Isles (○). Seasonal values are marked with a letter. Points with no letter refer to the full year.

with the ends of the  $L_2$  ( $W$ ),  $L_2$  ( $E$ ) and  $L_2$  ( $S$ ) vectors arranged clockwise about the  $L_2$  ( $Y$ ) value. In this case, however, the range of the seasonal variation is less at Tananarive than in Britain.  $L_2$  ( $Z$ ) shows a significant increase in amplitude from  $S$  to  $W$  at Tananarive. As might be expected for a southern observatory, the sign of  $L_2$  ( $Z$ ) is opposite to that for Britain.

I thank M. Burgaud for providing the data and for clarifying some details concerning these data.

### Daily Variation of Total Magnetic Field over the British Isles

THE use of observatory data as a basis for the correction of diurnal variation in magnetic surveys is common both for secular repeat stations spread over a wide area, and in ground and marine magnetic surveys where limitations of personnel and equipment prohibit the maintenance of a local base. Geographical interpolation of the variations is usually based on local time and latitude, the errors involved in this procedure being assumed to be small. In 1918, Walker<sup>1</sup> stated that such interpolation was incorrect, although he was prevented by the First World War from carrying out investigations to provide a more rigorous alternative. So far as I am aware, the situation today is little changed, at least in the British Isles.

During the reduction of a total field survey in North-West Ireland, comparisons between a local diurnal base station and Valentia Observatory suggested that differences were neither small nor clearly dependent on local time but were nevertheless systematic. It was therefore decided to investigate on a larger scale the inter-relationships of the daily variations over the British Isles with a view to determining whether the common interpolation method did provide agreement with the observations and to assessing the errors involved in using it.

Owing to the time lag in production of year books and to the closing down of Abinger Observatory, it was found most convenient to use published observatory data for the years 1956 and 1957. The figures used were those for the "Mean Diurnal Inequalities", that is the hourly means expressed relative to the mean of the period 0001–2359 G.M.T. Data from the French Observatories differed slightly from this, the tables in the year books giving the actual observed value at the hour rather than a mean, centred at 30 min past. The periods considered were for all days of the year and for the International Quiet Days of the summer (that is May, June, July and August), the latter probably being the period when the signal to noise ratio of the solar daily variation would be at a maximum.

Comparison of the phase and amplitude of the field variations at two stations was made by direct cross-multiplication and the calculation of the correlation coefficient, the process being simplified by the fact that the mean of the twenty-four values was by definition zero. As the use of the hourly values could only give a phase comparison to the nearest half hour, it was found necessary to interpolate values at 6 min intervals from a smoothed curve drawn by eye through the hourly means. Although this could introduce an unwelcome subjective element into the calculations, the pattern and consistency of the results would seem to justify the use of this smoothing in a preliminary analysis. By progres-

sively cross-multiplying the twenty-four values for one station with the series of twenty-four values of another station obtained at the hour, 6 min past, 12 min past, etc., the position of maximum correlation between the two curves could be placed to within  $\pm 2$  min. The mean of the two linear regressions obtained was taken as the measure of the amplitude relationship. The smallest value of the maximum correlation coefficient between two stations for all the comparisons was 0.88, still highly significant for twenty-four values.

Having thus obtained a network of links between stations, values of phase and amplitude at any particular station were expressed relative to Valentia Observatory by calculating a weighted mean for the station of the phases and amplitudes indicated by the link or links between it and Valentia, the weighting being proportional to the correlation coefficients of the links involved. The range of values for any one station, given by these links before taking the mean, was of the order of  $\pm 3$  min for phase and  $\pm 1$  for amplitude where Valentia is taken as 100 units.

The results pertinent to 1956 and 1957 from six observatories are shown in Table 1. As far as their consistency is concerned, there is a marked difference between the values obtained for the International Quiet Days of

the summer and those for All Days of the year. Within these two categories consistency is fair, apart from the phase values at Nantes and the International Quiet Days amplitude values at Chambon. Clearly the variations of the calculated values indicate that the relationships between stations are by no means constant but can change considerably in response to factors which are not at this stage possible to evaluate. Similar calculations on a series of observations made near Dublin suggest that in fact these relationships may even change from day to day. Using these data, Fig. 1, although it contains some values for one year only, shows the resultant contour maps of mean phase and amplitude for All Days of 1956 and 1957 and for the International Quiet Days of the summers of the same years. Also included in brackets are values of phase and amplitude obtained from the data given by Hill and Mason<sup>2</sup> for the one day, 26.6.61, at Ivybridge (near Plymouth) and Buoy 4 ( $47^{\circ} 22' N.$ ,  $07^{\circ} 37' W.$ ). This particular day, while not designated as an International Quiet Day, was not disturbed.

Despite the paucity of stations and the consequent uncertainty of contouring, two chief features seem to be evident in these maps. First, the amplitude of the daily variation of total field decreases eastwards; second, the

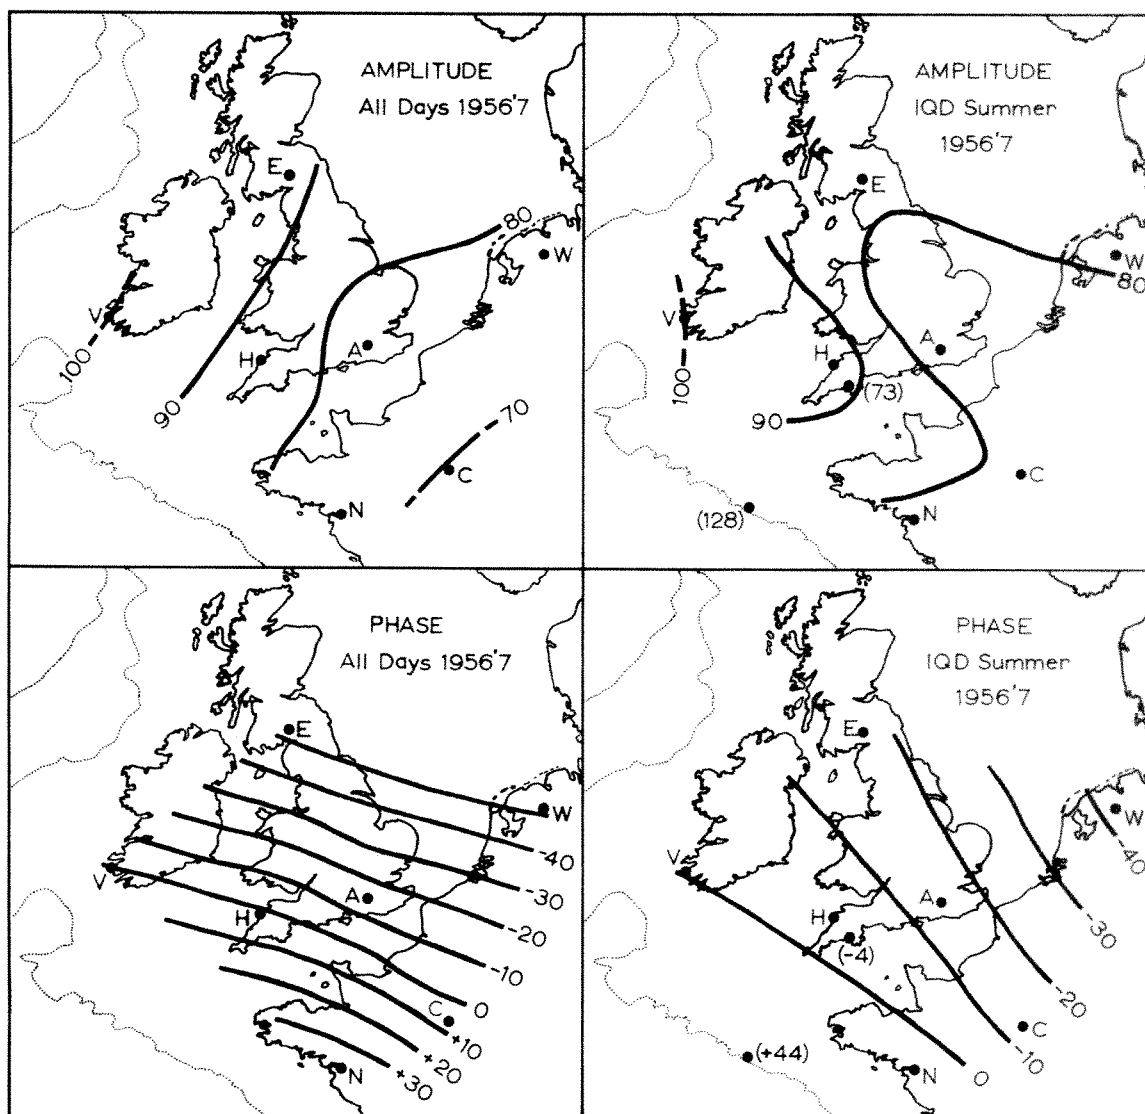

Fig. 1. Contours of phase and amplitude of diurnal variations of total field derived by linear interpolation from the data of Table 1. Amplitude relative to Valentia at 100 units, phase relative to Valentia in minutes; "before" shown negative and "after" positive. 1,000 fathom ocean contour shown dotted, observatories by initial letter.

Table 1. PHASE AND AMPLITUDE OF DIURNAL VARIATIONS OF TOTAL FIELD

Observatory	All days 1956	All days 1957	IQD Summer 1956	IQD Summer 1957
	Amplitude (Valentia 100 units)			
Valentia	100	100	100	100

Witteveen		-51		-42

\* Obtained from All Days of the summer because IQD data are not published.

contours of equal phase run approximately north-west-south-east, so that, for instance, the variation at Hartland occurs almost simultaneously with that at Valentia. Taking the contours for All Days as the norm around which other contour patterns will occur, the pattern contrasts considerably with the accepted "local-time" situation and shows some interesting correlations with the type of pattern predicted and discussed by Roden<sup>3</sup> for the edge of an ocean. In particular, the parallelism of the phase contours to the edge of the continent in the south-west as shown by the 1,000 fathom ocean contour, could compare in character with the model variations obtained by Roden for the Western Pacific. The amplitude contours show a decrease away from the edge of the Atlantic Ocean of the same order as predicted by Roden but are not so strikingly parallel to this 1,000 fathom ocean contour line.

A fuller analysis of the geography of the diurnal variations is obviously necessary before the theoretical implications can be properly discussed; however, the data calculated so far do suggest that the "local-time" method of applying diurnal variations over a wide area may be in need of modification, particularly in the light of the increased use of proton magnetometers giving absolute values of the field to  $\pm 1$  gamma. It is hoped

that an estimation of the relevance of shorter period (7-14 days) observations of phase and amplitude relationships to the overall picture may provide a basis for survey work from which a more detailed map of their normal distribution can be built up.

## Surface Air Radioactivity and Ozone at Amundsen-Scott Station (90° S.), Antarctica

THE Amundsen-Scott station located at the geographical South Pole offers, by virtue of its extreme isolation from man-made pollution, a unique setting for the study of atmospheric tracers. In addition, the permanent snow cover provides for the atmosphere a homogeneous, inert and unchanging lower boundary.

Continuous measurements of surface air radioactivity levels from 1959 to 1963 at the South Pole have previously been reported<sup>1</sup>. Additional data up to 1965, obtained with the same equipment, are presented. Surface ozone records for the period from 1962 to 1965 taken with two types of instruments, a Regener chemiluminescent device<sup>2</sup> and a Brewer-Mast wet chemical detector<sup>3</sup>, are also presented.

The monthly means for the airborne radioactivity (fission products), in c.p.m. (uncorrected) and in pc./100 m<sup>3</sup>, are shown in the lower half of Fig. 1. Above appear the monthly means of the surface ozone concentration, in parts of ozone per hundred million parts of air (p.p.h.m.), for the two types of instruments used. A comparison between the curves discloses a yearly oscillation of the fission products and of levels of ozone concentration in the surface air at Amundsen-Scott; furthermore, the respective oscillations are opposite in phase.

Fig. 1. Monthly means of ozone, in p.p.h.m., and radioactivity, in counts per minute (c.p.m.) or pico-curies per 100 m<sup>3</sup> (pc./100 m<sup>3</sup>) in the surface air at Amundsen-Scott station (90° S.).

In the middle latitudes of the northern hemisphere the time difference at the surface between the seasonal maxima for the same two tracers is approximately one month, with the radioactivity peak lagging<sup>4</sup>.

The six-month phase difference noted at the South Pole merits further investigation. It is possible that seasonal variations in the atmospheric exchange between the middle latitudes and the polar regions are somehow controlling the observed annual oscillation of ozone and radioactivity in the surface air at the South Pole.

### Implications of the Isotopic Ages of Ignimbrite Flows, Southern Atacama Desert, Chile

In the Andean Cordillera from central Chile to southern Peru, supergene alteration has been of profound economic significance to copper mining, because the unenriched hypogene assemblages rarely attain mineable grades in present conditions. The dimensions, grade, mineralogy and preservation of supergene enrichment zones in this region largely reflect the geomorphological evolution of the mineralized areas in the period since the orebodies were originally exposed.

We have carried out geomorphological studies<sup>1</sup> in the area between the Río Huasco (28° 40' lat. S.) and the Río Salado (26° 25' lat. S.) and have shown that the early stages of topographic development in this region are represented by a succession of extensive pediplains, and, locally, by aggradation deposits, which have accumulated on these erosion surfaces, in tectonic depressions, and in transverse river valleys. Acidic volcanic flows occur on the earliest recognizable surface or topography, on the lowermost and most recent major pediplain, and on and within the aggradation deposits.

Our systematic examination of the workings of the many small copper mines in the Copiapó region (27° 20' lat. S.) has shown the existence of at least two main zones of supergene sulphide enrichment, marked by the development of massive djurleite and subordinate chalcocite, blaubleibender covelline and covelline. In most parts of the area, the lower and more persistent of the enriched zones lies at or near the surface of the lowermost pediplain, and it is clear that the supergene alteration profile was truncated during the formation of this planation surface. We propose that most enrichment took place during the extended period in which the succession of pediplains was developed, but at times when pediplanation was relatively inactive.

In order to date the evolution of the landforms and the periods of supergene mineral alteration we have collected specimens of ignimbrite for potassium argon dating. The ignimbrite carries biotite and has the composition of a sodi-potassic rhyolite. So far two specimens from differing parts of the ignimbrite flow, which lies on the lowermost pediplain in the vicinity of the Quebrada San Andrés (IGS-67: 19, IGS-67: 44) in the Río Copiapó drainage basin, and single specimens from two ignimbrite sheets exposed in the canyon of the Río Salado, have been dated. Of the Río Salado flows, one (IGS-67: 40, from the vicinity of Pueblo Hundido) is interbedded with an alluvial sequence which forms part of the aggradation within the Longitudinal Valley of northern Chile, while the other (IGS-67: 45, from Potrerillos airport) lies on the surface of the aggradation deposits, and is clearly younger.

Particular care was taken in the separation of the biotite to exclude the minor amphibole of the sparse lithic fragments of andesitic material occurring in the non-welded ignimbrites. Potassium was determined by flame photometry, and argon measured by isotope dilution with enriched argon-38 on an A.E.I. 'MS.10' mass spectrometer.

Several conclusions may be drawn from the results (Table 1). The close correspondence of the two dates obtained for the Quebrada San Andrés ignimbrite flow suggests that they directly reflect the time of consolidation of the flow, and that contamination from all sources<sup>2</sup> has been insignificant. Furthermore, the minor apparent difference between the ages of the two Río Salado flows, although approaching the limit of precision of the analyses, nevertheless probably indicates the period in which the intervening alluvium was deposited.

Table 1. RESULTS OF POTASSIUM ARGON AGE DETERMINATIONS ON BIOTITES FROM IGNIMBRITES, SOUTHERN ATACAMA DESERT, CHILE

Specimen No.	Specimen location	Potassium (wt. per cent)	Vol. of radiogenic argon-40 (c.c./g of sample, S.T.P.) ( $\times 10^6$ yr)	Age and error ( $\times 10^6$ yr)	Mean age and error ( $\times 10^6$ yr)
IGS-67: 19	26° 55' lat. S. 69° 37' long. W.	7.29	$2.781 \times 10^{-6}$	$9.5 \pm 0.5$	9.15 $\pm 0.25$
IGS-67: 44	27° 07' lat. S. 69° 43' long. W.	6.91	$2.493 \times 10^{-6}$	$9.0 \pm 0.3$	
IGS-67: 45	26° 22' lat. S. 69° 29' long. W.	7.25	$3.335 \times 10^{-6}$	$11.5 \pm 0.5$	
IGS-67: 40	26° 21' lat. S. 69° 53' long. W.	6.96	$3.443 \times 10^{-6}$	$12.6 \pm 0.5$	

Isotope abundance: <sup>40</sup>K = 0.0119 atomic per cent

Decay constants:  $\lambda\beta = 4.72 \times 10^{-10} \text{ yr}^{-1}$

$\lambda e = 0.584 \times 10^{-10} \text{ yr}^{-1}$

The new data show that eruption of ignimbrites, presumably from vents in the high Andes to the east of the area, occurred between  $12.6 \pm 0.5$  and  $9.15 \pm 0.25 \times 10^6$  yr B.P., in the Upper Miocene<sup>3</sup>. These volcanics are therefore to be included in Brüggén's 'Formación Liparítica'<sup>4</sup>, the extrusion of which has been shown to have persisted at least from  $18.7$  to  $2.9 \times 10^6$  yr B.P., in northern Chile<sup>5</sup>. Ages within this range have also recently been obtained for acidic volcanics in the region of San Pedro de Atacama, Antofagasta Province<sup>6</sup>.

The ages of the Río Salado ignimbrites show conclusively that aggradation in this area commenced appreciably earlier than  $12.6 \pm 0.5 \times 10^6$  yr B.P., and had terminated by  $11.5 \pm 0.5 \times 10^6$  yr B.P. Previous workers have suggested an Upper Pliocene<sup>7</sup> or Quaternary<sup>8</sup> age for these deposits, but our studies establish a markedly older time of formation. The dates suggest that the rate of aggradation in the Río Salado area was very slow; considerably less than 100 m of detritus was deposited in a maximum period of  $2.1 \times 10^6$  yr. Since the extrusion of the younger ignimbrite, the only apparent topographic changes in this stretch of the Río Salado valley have been the cutting of the canyon, followed by limited aggradation in the canyon floor.

The dates obtained for the Quebrada San Andrés flow indicate that the underlying, youngest pediplain in this area was in existence before  $9.15 \pm 0.25 \times 10^6$  yr B.P. Here it is again evident that the landscape of this region of the Andes has suffered remarkably little modification since the Upper Miocene; the erosion surface has been dissected, however, and restricted alluviation has occurred in the floors of the resulting shallow valleys. Recent topographic changes have, however, taken place in the coastal region which was directly affected by movements of sea level and local tectonic displacements.

On the basis of the deformation of ignimbrite flows in the San Pedro de Atacama region, Rutland *et al.*<sup>9</sup>, in agreement with earlier views<sup>8</sup>, have suggested that the chief Andean uplift occurred over an extended period from the Upper Miocene to the Pleistocene. In the southern Atacama Desert, ignimbrite flows cover a more restricted area, and a comparable ignimbrite stratigraphy is lacking, but our present evidence suggests that tectonic

activity in Pliocene and more recent times has been of little fundamental importance in this area.

On limited stratigraphic evidence, it has been suggested that the supergene enrichment of the Chuquicamata and Potrerillos porphyry copper deposits in northern Chile<sup>9,10</sup> and of deposits in southern Peru<sup>11</sup> occurred beneath an extensive erosion surface, the *Puna*, which developed in the period between the Eocene earth movements and the Andean uplift (of presumed Plio-Pleistocene age). Segerstrom<sup>12</sup>, on the other hand, proposed that enrichment in much of northern Chile resulted from the formation of a mid-Tertiary "matureland", but in our recent work we have been unable to recognize remnants of such a "matureland" in the essentially polycyclic landscape of the Copiapó region. The dating of the ignimbrites, however, yields a minimum age for the supergene alteration which does not contradict the conclusions of earlier workers. The observed inter-relationships of supergene alteration, pediplanation, and ignimbrite eruption in the Copiapó area clearly demonstrate that all important enrichment was completed before the end of Miocene times (before  $9.15 \pm 0.25 \times 10^6$  yr B.P.). Estimation of the maximum age of the enrichment must await the determination of the age of the volcanics which were extruded onto surfaces which existed before the development of the supergene alteration zones.

These new data contribute to the establishment of an absolute chronology of topographic evolution and supergene alteration in the southern Atacama Desert, and, on a broader scale, imply that important enriched zones may be preserved in copper deposits concealed beneath volcanics and aggradation of Mio-Pliocene age elsewhere in northern Chile<sup>13</sup>.

## The Arctic Mid-Oceanic Ridge

THE Mid-Oceanic Ridge, a broad fractured arch more than 40,000 miles long, is the largest tectonic feature on the surface of the Earth. Associated with the centre

of the ridge over much of its length is an axial fracture or rift which is the locus of shallow earthquakes. An extension of this world encircling ridge into the Greenland Sea and Arctic Ocean was first hypothesized on the basis of a well defined pattern of earthquake epicentres and a few spot soundings<sup>1,2</sup>. The topographic form of the ridge was first revealed by precision depth records obtained during the pioneer polar crossings of the nuclear submarines *Nautilus*<sup>3</sup> and *Skate*<sup>4</sup>. The Arctic Mid-Oceanic Ridge does not bisect the entire Arctic Basin but lies midway between the monolithic, aseismic Lomonosov Ridge and the Eurasian continental margin.

The Arctic Mid-Oceanic Ridge is flanked by abyssal plains. The Pole abyssal plain<sup>5</sup> which lies between the ridge and the aseismic Lomonosov Ridge is deepest near the Pole; this suggests that the primary source of sediment is from the two landward ends near Greenland and off the Lena Delta. Prominent sub-bottom reflectors, usually three in number, are observed on echograms from the deepest portion of the abyssal plain (Fig. 1, profile 4). Sub-bottom layers are usually detected only near the distal ends of abyssal plains where the ponded clays form thick transoral layers.

The existence of the Barents abyssal plain between the Arctic Mid-Oceanic Ridge and the Eurasian continental shelf originally predicted by Heezen and Laughton<sup>6</sup> is confirmed by recent sounding profiles (profiles 3-5). The Barents abyssal plain has an appreciable slope from east to west indicating the dominance of the Ob and Yenisey rivers as sources of sediment<sup>6</sup>.

Within 10° of the Greenwich meridian the ridge has a width of approximately 150 miles (profiles 5 and 6). Flanking topographic highs border a depressed axial valley. This valley is strikingly developed in the area north of Spitsbergen (profile 6) where it is 2,800 fathoms deep in contrast to the adjacent rift mountains which are only 1,600 fathoms deep.

The axis of the Mid-Oceanic Ridge is characteristically offset at intervals by fracture zones which cut across the ridge at approximately right angles to its axial trend. The Arctic Mid-Oceanic Ridge ends abruptly in the continental margin of Greenland. This sudden termination (profiles 6 and 7) suggests the existence of a N.N.W. extension of the Spitsbergen Fracture Zone<sup>4</sup> which may be masked by the sedimentary blanket<sup>7</sup> of the Greenland continental margin.

The Mid-Oceanic Ridge off the Laptev and Kara Seas (profiles 2-4) is a relatively subdued feature. The flat portions of the sea floor (profile 3) might be interpreted as segments of the Pole abyssal plain elevated by the growing ridge. But the more likely interpretation seems to be that the sediment continuously poured into the Arctic Basin by the Lena, Ob and Yenisey rivers has been sufficient in quantity to bury the eastern end of the ridge continuously. The multitude of hyperbolic echoes which are reflected from the uneven surfaces of the ridge along the belts of the epicentre indicates continuing tectonic activity, but the subdued relief suggests that the growth of the oceanic crust is taking place beneath a blanket of sediments (profile 1).

Magnetic anomalies<sup>7,8</sup> over the Arctic Mid-Oceanic Ridge have very small amplitudes as compared with the Mid-Atlantic Ridge. Dementitskaya and Karasik<sup>9</sup>, however, report that a well defined pattern of linear axially oriented magnetic anomalies is associated with the ridge. The thick blanket of sediment which covers the growing ridge may raise the level of the Curie isotherm and diminish the amplitude of the magnetic anomalies. A similar dampening effect has been observed in the Red Sea<sup>10</sup> north of 23° where the axial trough is buried under a thick sedimentary cover; it has also been observed in the northern Gulf of California<sup>11</sup>.

The suggestion of Heezen<sup>12-14</sup> that the Mid-Oceanic Ridge has grown wider with time by the continuing emplacement of mantle derivatives in an ever-widening

Fig. 1. Tracings of precision echograms (PDR) obtained by submarines in the Arctic. Transducer depth is not computed. Profiles 5 and 7 taken from Skate<sup>4</sup>. Small dots on index chart are earthquakes<sup>14</sup>.

rift valley has received important support from the palaeomagnetic interpretation of geomagnetic traverses of total intensity<sup>15</sup>.

Crustal growth along the present Arctic Mid-Oceanic Ridge has gradually separated the aseismic Lomonosov Ridge from the Eurasian continent. Alpha Ridge—a subdued feature which lies between the Lomonosov Ridge and the continental margin of American and western Siberia—may represent a former axis of crustal growth.

## Carbonatite and Alkaline Igneous Rocks in the Brent Crater, Ontario

THE Brent crater (46° 04' N., 78° 29' W.) is cut into the Pre-Cambrian gneisses of central Ontario. On the surface the crater is marked by a poorly defined depression 18,000 ft. in diameter, with a sharply defined central crater 11,000 ft. in diameter and about 200 ft. deep. Drilling<sup>1</sup> has shown that the central crater is partly filled with flat lying Ordovician strata underlain by a thick lens of brecciated Pre-Cambrian material. A hole drilled approximately in the centre of the structure<sup>1,2</sup> passed through about 800 ft. of Ordovician strata, 1,900 ft. of breccia of various kinds, and beginning at a depth of 2,716 ft. penetrated breccia with a matrix of igneous textured trachyte for more than 100 ft. Below this "melt zone" brecciation died out very rapidly. Because of petrographic features found in the breccias, Brent has been widely accepted as a holotype of a "fossil" meteorite crater<sup>1-4</sup>. The Brent crater occurs on or near the Ottawa-Bonnechere graben, however, a major structure with a length of some hundreds of miles<sup>5</sup>, along which circular alkaline and carbonatitic complexes were intruded in Cambro-Ordovician time<sup>6,7</sup>. These facts suggest a possible endogenetic origin for the crater. In an attempt to resolve this problem we examined the petrographic and chemical composition of twenty-three samples of drill core from the central hole and nine samples collected on the surface. It was found petrographically that the samples fell into four groups. Underlying the Ordovician were about 100 ft. of breccias with substantial amounts of glass (often of several types), below which were 1,700 ft. of breccias with little or no glass. At a depth of 2,700 ft., 16 ft. of breccia rich in glass was again encountered

Table 1. AVERAGE COMPOSITION OF ROCK UNITS FROM THE BRENT CRATER, ONTARIO

a, Trachytic igneous rocks (3 samples); b, glass rich breccia (6 samples); c, glass poor breccia (6 samples); d<sub>1</sub>, country rocks from drill cores (7 samples); d<sub>2</sub>, country rocks from surface (9 samples); e, vein cutting glass poor breccia; s, standard deviation of average analysis.

The last four columns show whether differences between units are significant at the 1 per cent level.

grading into inclusion rich trachyte of igneous aspect. About 50 ft. of breccia rich in glass occurred below the trachyte, passing abruptly into relatively undeformed country rocks. A specimen from one of the dykelets cutting the breccia poor in glass was composed of extremely fine grained carbonates, minute needles of a pleochroic blue mineral and abundant opaque dust.

The average composition and standard deviation of each of these petrographically defined units is given in Table 1. The compositions were obtained by direct reading spectrography for SiO<sub>2</sub>, Al<sub>2</sub>O<sub>3</sub>, total iron, CaO, MgO and TiO<sub>2</sub>, by emission spectrography for beryllium, boron, barium, nickel, cobalt, chromium, copper, vanadium and zirconium, and by wet chemistry for nickel, cobalt, copper, lead and zinc. Potassium and sodium were analysed by flame photometry. Analysis of standards G-1, T-1 and W-1 by the same methods suggests that the average error for the principal elements is about 4 per cent of amount present.

Student's *t* test with the Bessel correction for small samples has been applied to Table 1 to detect the differences between units. The agreement between the two samples of country rocks is excellent, showing that a satisfactory mean composition was achieved by the number of samples used. The breccias free of glass differ significantly from the country rocks only in a greater content of MgO. The igneous rocks and breccias rich in glass are notably similar in composition, but they differ significantly from the other two units for thirteen of the nineteen elements analysed. Both rocks are strongly potassic and characterized by a dominance of MgO over CaO unusual for such silicic rocks. The dyke rock is alnoitic in chemical composition (compare Table 2). The composition prompted a semi-quantitative spectrographic search for rare earths. Niobium and cerium were the only rare earths found in detectable amounts. The dyke

rock has a very high heavy metal content. In Table 2 analyses from Brent are compared with rocks from various alkaline and carbonatite complexes.

To summarize, potassic trachytes associated with alnoite have been found at depth in the Brent structure. The geometric form of these rocks is unknown. Breccias rich in glass and similar in composition to the trachyte are found above and below it at the top of the structure, where rocks of igneous appearance have not as yet been discovered. The composition of these breccias implies strong enrichment of potash and magnesium together with depletion of sodium and calcium, so that the breccias could be fenites.

The Brent structure occurs in an area of known alkaline carbonatite activity, on or near a structure known to be associated with such activity. The age of igneous activity is the same as that of the Brent structure, as nearly as is known<sup>6</sup>. The size and general disposition (breccia funnel with igneous rocks at depth) of the Brent structure is compatible with that of known alkaline carbonatite complexes elsewhere<sup>8</sup>. Petrographic observations<sup>2,3</sup> have hitherto been thought to demonstrate an impact origin for the Brent crater, but the petrochemistry of the rocks strongly suggests that the Brent structure is an alkaline carbonatite complex. The implications drawn from the petrographic data must therefore be reassessed.

We thank the Dominion Observatory of Canada for providing samples, R. E. Horton and C. C. Durham for spectrographic analyses, and J. J. Lynch for wet chemical analyses.

## PHYSICS

## Timing of Sonoluminescence Flash

It has been pointed out<sup>1</sup> that theories attempting to explain the origin of the sonoluminescent flash, which is sometimes observed in acoustic cavitation, can be divided according to whether they predict the flash to occur at the moment of birth or collapse of the bubble.

Negishi<sup>2</sup> has shown that light is emitted when the bubble volume is at a minimum, and this is taken to favour the second class of theories. It also appears, however, that individual cavitation bubbles may rebound or re-form for many cycles of the acoustic field<sup>3</sup>. In this case, it is not possible to distinguish with certainty between the collapse and birth, or rebirth, time. Furthermore, it was shown that then only one flash is usually emitted which is followed by a series of rebounds lasting for some milliseconds. The only obviously unique occasion when the bubble volume is at a minimum is at the initial birth, which in Hahn's case<sup>3</sup> was nucleated by fast neutrons from an isotope source.

We have carried out similar experiments in which cavitation bubbles are nucleated by fast neutrons from a pulsed source. The time delay between the neutron burst and the emission of the flash was observed, using a 100 channel time sorter on 1  $\mu$ sec channels. The flash was not emitted during the burst, that is, at the time of nucleation and the initial growth of the bubble, but on average more than half a period of the sound wave later.

Two 1 in. photomultipliers were arranged to view the central pressure maximum of a cylindrical glass container of liquid, excited in the 101 mode by a barium titanate ring cemented to the outside of the container. The liquid used was degassed tetrachloroethylene and the exciting frequency about 20 kc/s, the sound pressure amplitude being 10–15 atm. peak. A block diagram of the electronics is shown in Fig. 1. The outputs from the photomultipliers were arranged in coincidence, and provided a stop pulse for the 100 channel analyser. An 8 pulses/sec pulser (not phase locked to the 20 kc/s sound wave) triggered the neutron generator, a modified Elliot K-tube generator, which accelerates deuterons from a plasma onto a tritiated target to produce a 2  $\mu$ sec wide burst of 14.3 MeV neutrons. A magnetic field is used to assist in the production of the deuterium plasma and there is a delay of about 60  $\mu$ sec after the trigger pulse while this field is established and before the neutron burst. A delay unit was arranged to start the sweep of the time sorter approximately 12  $\mu$ sec before the neutron burst. The neutron intensity was adjusted to give approximately two bubbles/sec, that is, only about one neutron burst in four resulted in bubble nucleation.

The time spectrum obtained in this way is shown in Fig. 2. It is clear that there is a long delay between the burst and the emission of the sonoluminescent flash. There are 1,376 counts in the spectrum. When the liquid container was replaced with a cylinder of plastic scintillator, a single sharp peak about 2  $\mu$ sec wide was observed in the spectrum at the point marked "neutron burst time".

Fig. 1. Block diagram of the electronics of the experiments.

Fig. 2. The time spectrum of sonoluminescence flashes. The spectrum is made up of a total of 1,376 counts.

The rise time of flash, as observed by the photomultipliers, was not greater than 12 nsec.

### Upper Limit on the Abundance of Anti-protons in the Low Energy Galactic Cosmic Radiation

THE existence of anti-matter in the universe has intrigued astrophysicists for quite some time. Several authors have suggested the existence and creation of anti-matter at various places in the universe<sup>1,2</sup>. One way of attempting to verify such possibilities is to see if cosmic rays, which include nuclei accelerated from various regions of our galaxy (if not the whole universe), contain anti-nuclei. Alfven<sup>1</sup>, however, argues that cosmic rays at the Earth may not contain anti-nuclei for various reasons. Even if this were so, cosmic rays should contain secondary anti-protons produced in collisions of cosmic ray protons with interstellar hydrogen. Estimates of the abundance of secondary anti-protons have been made by several authors: Fradkin<sup>3</sup> gives a value  $(\bar{p}/p) \sim 5 \times 10^{-4}$  for anti-protons of energy  $E_p > 1.7$  GeV; Milford and Rosen<sup>4</sup> estimate that for  $E_p \sim 0.5$  GeV,  $(\bar{p}/p) \leq 3 \times 10^{-3}$  and more recently by calculating the energy spectrum of such anti-protons they state<sup>5</sup> (the numbers are not published to my knowledge) that the ratio  $(\bar{p}/p)$  at low energies may be greater by several orders of magnitudes than that calculated at high energies.

There have been several attempts made in the past to detect anti-nuclei with charge  $Z \geq 6$  in cosmic radiation<sup>6-8</sup>. These experiments consisted of examining the ends of tracks of cosmic ray nuclei, brought to rest in nuclear emulsions, for characteristic annihilation interaction. No such nucleus has been detected so far; therefore upper limits have been set to the ratio of these anti-nuclei to normal nuclei<sup>6-8</sup>, the lowest being  $10^{-3}$ . If anti-nuclei exist in the cosmic rays at balloon altitudes, however, it is likely that they exist as anti-protons, because the mean free path of anti-nuclei ( $Z \geq 6$ ) for annihilation ( $\sim 3$  g/cm<sup>2</sup> of hydrogen) is much smaller than that of anti-protons ( $\sim 18$  g/cm<sup>2</sup>) and the nuclei are observed after crossing several g/cm<sup>2</sup> of interstellar hydrogen. Aizu *et al.*<sup>7</sup> have examined the stopping ends of singly charged nuclei obtained in their experiment, and give an upper limit for the ratio  $(\bar{p}/p)$  as  $10^{-3}$ , assuming that all the singly charged nuclei which they observed were of cosmic origin.

In the present experiment, we used a nuclear emulsion stack exposed at Fort Churchill, Canada, on August 4, 1962, for 13 h 52 min under 4.2 g/cm<sup>2</sup> of residual atmosphere. The stack consisted of nineteen Kodak 'NTB-4' emulsions each 625 $\mu$  thick. The experimental procedure consisted in looking for the "signature" of an anti-proton, which is an interaction or "star" produced by an incoming slow particle in the nuclear emulsion with at least one minimum ionizing singly charged particle track (pi-meson) associated with it. Microscope scanning was first performed for all interactions; each interaction observed was then examined under high power to select those which had at least one minimum ionizing particle track\*. In order to find whether there is any incoming slow particle associated with the selected stars, all tracks in the upper hemisphere with ionization greater than six times that of a relativistic particle were traced through the stack until they either came to rest or left the emulsion stack. If the track left the stack, measurements of the ionization, one near the interaction and a second near the exit, were made. The change in ionization, if any, indicates the direction of motion of the particle. It is easy to see that in the case of a genuine anti-proton annihilation star, the track of the incoming anti-proton will show an unambiguous and easily detectable change of grain density and Coulomb scattering.

A total volume of 4.5 c.c. from three emulsion plates has so far been scanned. About 5,000 stars from this scan have been examined for the anti-proton signature. Only one anti-proton star was found; the anti-proton producing this interaction, however, came from another interaction within the emulsion stack itself. No anti-proton coming from outside the stack was observed.

In order to obtain an upper limit on abundance ratio of anti-protons to protons ( $\bar{p}/p$ ) for the cosmic ray, we have to know the number of primary protons that would have stopped in the volume scanned. This number has been calculated using a flux of 0.4 protons per (m<sup>2</sup>.sec.ster.MeV)<sup>10</sup>. In this calculation protons with zenith angles greater than 60° have been neglected, because in our experiment, tracks with such large angles will be steep in the emulsion plate with a possible reduction of efficiency in tracing and other procedures. The energy of protons that would have stopped in the scan volume is between 100 and 150 MeV and the total number of such protons relevant to our experiment has been calculated to be about 3,500. If one anti-proton had been found in this experiment, the ratio ( $\bar{p}/p$ ) would have been about  $3 \times 10^{-4}$  so that the upper limit can be set as  $(\bar{p}/p) \leq 3 \times 10^{-4}$ .

The upper limit given here, however, is much lower than the value suggested by Rosen and Milford<sup>5</sup>.

I thank Professors R. R. Daniel and S. Biswas for critical comments and Miss Aruna Chitnis for help with the scanning procedures.

\* About 6 per cent of anti-proton interactions do not produce even one charged relativistic pi-meson (minimum ionizing track), so that these will be missed. The average number of relativistic charged pi-mesons produced in an anti-proton interaction in emulsion is  $2.6 \pm 0.3$  (ref. 9). The number of black prongs associated with a star with one or two pi-mesons is on the average five to six. As the charged pi-meson number increases to five the black prong number falls to about two\*. In either case then, as a result of the large size of the stars, scanning losses are negligible.

## Short-range Dating of Fresh Nuclear Debris

FRESH nuclear debris particles were detected in ground air and rain water at Niigata, Japan, on May 11, on November 1 and on December 30, 1966. Without doubt, the particles collected on May 11 resulted from a Chinese nuclear test conducted at 1700 h (Japanese time) on May 9, 1966. These particles of known origin provided a favourable opportunity to examine a rapid method for dating of nuclear debris particles shortly after their formation.

Fig. 1. Variation of ratio of <sup>97</sup>Zr : <sup>95</sup>Zr after the explosion. ○, Explosion on May 9, 1966; ●, explosion on December 28, 1966.

The determination of the activity ratio of a short-lived (1 day) to a relatively long-lived (10–100 days) fission product in a debris particle at a given time after a nuclear fission process can be used as a sensitive test of the age of nuclear debris. Of many available pairs <sup>97</sup>Zr and <sup>95</sup>Zr, <sup>133</sup>I and <sup>131</sup>I, and <sup>143</sup>Ce and <sup>141</sup>Ce are considered most useful for a number of reasons. For example, the fractionation behaviour during the formation of debris between the respective isotopes is similar and radiochemical analyses can be rapidly and simply carried out. We chose the pair <sup>97</sup>Zr and <sup>95</sup>Zr because they exhibit a similar fractionation behaviour; the decay chain of <sup>97</sup>Zr is 17h, <sup>97</sup>Zr → 60s, <sup>97m</sup>Nb → 73m, <sup>97</sup>Nb → stable <sup>97</sup>Mo. Because the half lives of <sup>97m</sup>Nb and <sup>97</sup>Nb are much shorter than that of <sup>97</sup>Zr, a state of radioactive equilibrium is established immediately after the formation of <sup>97</sup>Zr. Some precursors of <sup>97</sup>Zr and <sup>95</sup>Zr are gaseous or volatile elements, for example, bromine, krypton and rubidium, but their half lives are all so short that no significant fractionation effect would be expected between the two isotopes during particle formation<sup>1</sup>. Measurement of the activity ratio of <sup>97</sup>Zr : <sup>95</sup>Zr in a single particle can thus provide a simple method for determining its age.

Some highly fractionated particles of larger size—more than 10 $\mu$  in diameter—consisted mainly of short-lived refractory fission products such as <sup>97</sup>Zr, <sup>99</sup>Mo and <sup>143</sup>Ce with no detectable amount of <sup>132</sup>Te, <sup>132</sup>I and <sup>133</sup>I. In this case, activities of the radiozirconium were directly measured with no chemical separation. To do this we used a 1½ in. × 1 in. sodium iodide scintillation detector with a 200 channel pulse-height analyser, and determined the activities by measuring the area of the photopeaks. Many of the particles, however, contained a considerable

amount of the short-lived volatile fission materials  $^{132}\text{Te}$ – $^{132}\text{I}$  and  $^{133}\text{I}$ , and therefore after the samples had been fused with sodium carbonate they were dissolved in nitric acid. The sample solution was then analysed by a TTA–xylene extraction method<sup>2</sup> and the purified radiozirconium sample submitted to  $\gamma$ -spectrometric measurement.

Fig. 1 shows the measured activity ratio of  $^{97}\text{Zr} : ^{95}\text{Zr}$  (open circles) plotted as a function of time 2–7 days after the explosion, together with an assumed line (solid line) of the time variation in the  $^{97}\text{Zr} : ^{95}\text{Zr}$  ratio. The line is plotted against time on the assumption that cumulative fission yields of  $^{97}\text{Zr}$  and  $^{95}\text{Zr}$  are 5.9 and 6.2, respectively<sup>3</sup>. The single particle used for these measurements was spherical in shape,  $16\mu$  in diameter, reddish brown in colour and had a total  $\beta$ -activity of  $2.1 \times 10^6$  pc. at 1300 h, May 11. As can be seen from the figure, most of the results seem to lie along the assumed line. Thus it would seem that no enrichment of  $^{97}\text{Zr}$  relative to  $^{95}\text{Zr}$  occurred in the particle. As a result, it was possible to calculate an age for it, without making any corrections for fractionation, by comparing a measured activity ratio of the two isotopes with a corresponding value on the assumed line. The results obtained are given in Table 1. It can be seen that most of the estimated ages agree with the values calculated from the known time of explosion for the May 9 nuclear test; they do so especially well within 5 days of the explosion. Thus it would seem possible that when two nuclear explosions are conducted with a time interval of more than 10 h between them, particles released from them can be distinguished by measuring their activity ratio of  $^{97}\text{Zr} : ^{95}\text{Zr}$  for up to a week after their formation.

Table 1. CALCULATED AND ESTIMATED AGES AT DIFFERENT TIMES OF A SINGLE FALL-OUT PARTICLE OF KNOWN ORIGIN

Date of measurement	Age since the formation Calculated* (h)	Estimated (h)
1000 h, May 11, 1966	41	41
1000 h, " 12 "	65	66
1100 h, " 13 "	90	91
1100 h, " 14 "	121	116
1300 h, " 15 "	140	138
1300 h, " 16 "	164	172

\* These figures were calculated on the basis of the time of explosion—1700 h, May 9, 1966 (Japanese time)—given by the responsible Chinese agency.

Table 2. ACTIVITY RATIO OF  $^{97}\text{Zr}$  to  $^{95}\text{Zr}$  AND ESTIMATED AGE OF FRESH NUCLEAR DEBRIS PARTICLES COLLECTED ON DECEMBER 30, 1966

Date of measurement	Activity ratio	Estimated age (h)
2300 h, Dec. 30, 1966	9.0	56 (1500)*
1100 h, " 31 "	5.3	69 (1400)
2100 h, " 31 "	3.7	77 (1600)
1400 h, Jan. 1, 1967	1.7	97 (1500)
1700 h, " 2 "	0.67	120 (1700)
1400 h, " 3 "	0.24	145 (1500)
1400 h, " 4 "	0.09	170 (1200)

\* The figures in parentheses refer to assumed times of explosion on December 28, 1966, calculated from each of the respective ages estimated.

In order to test this method of age determination, we estimated the age of hot fall-out particles collected on December 30, 1966, at Niigata. As the radiozirconium content in a single particle collected on December 30 was too small to determine the activity ratio of  $^{97}\text{Zr} : ^{95}\text{Zr}$  with a sufficient accuracy—less than one-two-hundredth that of the May 9, 1966, test—a composite sample of fifty-five particles was used for measurement. The ratios were determined at different times after collection using a chemically purified sample of radiozirconium. Table 2 shows the activity ratios of  $^{97}\text{Zr} : ^{95}\text{Zr}$  measured during the period December 30, 1966–January 5, 1967 (solid circles in Fig. 1), and the estimated ages at different times of the composite sample. They were also evaluated by a comparison of their  $^{97}\text{Zr} : ^{95}\text{Zr}$  ratios with the corresponding values on the assumed line (Fig. 1). From the ages thus obtained, we conclude that the explosion from

which these hot particles originated was probably between 1200 and 1700 h (Japanese time), December 28, 1966.

## CHEMISTRY

### Irradiation and the Subsequent Solid State Thermal Decomposition of Silver Nitrite

We have examined the thermal decomposition of solid silver nitrite at  $50^\circ\text{C}$  after it has been exposed to  $\gamma$ -radiation from a cobalt-60 source (dose rate at the sample =  $1.5 \times 10^4$  r./h). The kinetics were followed gravimetrically *in vacuo* using collections of many well formed single crystals (sample size about 10 mg). The results are shown in Fig. 1. In contrast with results found in decomposition studies of other solids, which have shown either an enhancement of rate or negligible effect following irradiation<sup>1</sup>, with silver nitrite there is a marked inhibition in the rate of decomposition with the dose of  $\gamma$ -rays. There was no significant loss in weight of the sample during irradiation. The irradiation was performed *in vacuo*. If the irradiation was carried out in a poor vacuum or at 1 atm. there was no effect on the subsequent thermal decomposition. This finding is of considerable importance because it may apply to the study of radiation damage in other reversible solid state decomposition reactions of the type  $A_{(s)} \rightarrow B_{(s)} + C_{(g)}$ .

The kinetics of the thermal decomposition of unirradiated silver nitrite have been examined from  $35^\circ\text{C}$  to  $90^\circ\text{C}$ . The decomposition of both irradiated and unirradiated silver nitrite continues to completion ( $100 \pm 3$  per cent), that is,  $\text{AgNO}_{2(s)} \rightarrow \text{Ag}_{(s)} + \text{NO}_{2(g)}$ , if the nitrogen dioxide is continually removed during a run. It was found that the rate constants determined from the slope of the extensive linear region (15–45 per cent) in the decomposition curves (Fig. 1) for runs at temperatures above  $60^\circ\text{C}$  fell below the extrapolated Arrhenius plot as determined from data at lower temperatures. This fall-off is believed to result mainly from inhibition by gaseous

Fig. 1. Fraction decomposed,  $\alpha$ , versus time plots for the decomposition of irradiated silver nitrite at  $50^\circ\text{C}$ . Exposure time in hours: A, 0; B, 1; C, 2.5; D, 5; E, 10; F, 20 (dose rate  $1.5 \times 10^4$  r. h<sup>-1</sup>).

products, that is, even with direct evacuation the gases are evolved too rapidly to be removed. For this reason most effort has been concentrated on slow runs, at temperatures below 60° C; this, of course, also minimizes any errors arising from self-cooling. It should be noted that the lowest temperature at which this reaction previously appears to have been studied is 72° C (ref. 2).

Boldyrev and Eroshkin<sup>2</sup> have recently observed similar behaviour when silver nitrite is irradiated with X-rays before decomposition (80° C). Their results show an inversion effect, that is, at higher doses the rate increases relative to lower doses. This behaviour was not observed in our work. Their inversion effect occurs at a relatively low level of inhibition when compared with the more marked inhibitory effects observed in the present data. Because this reaction is sensitive to the presence of gaseous products both during the irradiation and the subsequent thermal decomposition, we suggest that the inversion which they observed is an experimental artefact and may result from inhibition by gaseous products.

This investigation was supported in part by a US Public Health Service fellowship from the National Institute of General Medical Sciences to J. W. S. We gratefully acknowledge the co-operation of Dr. D. J. Smith in the use of the cobalt-60 source.

### Solubility of Cupric Oxide in Pure Water at Temperatures up to 550° C

WE report here work in progress on the measurement of the solubility of metals and metal oxides in pure water, in the temperature range 50°–550° C and at pressures up to 400 bars. The isobaric solubility of cupric oxide at 310 bars is reported here and compared with the 300 bar isobar for silica (quartz).

The solubility measurements were made by passing demineralized, distilled and de-aerated water, at the required temperature and pressure, through a packed bed of solute particles contained in an autoclave. To prevent carry-over of particulate material, the solution leaving the autoclave was filtered through a stainless steel frit (1  $\mu$ m pore diameter). It was then cooled at pressure to reduce deposition in the cooling system and passed through a back-pressure regulator to be collected for analysis. The high pressure water circuit was constructed from 'Nimonic' 80.4 and 90 alloys. For the cupric oxide-water system the samples of solution were collected in dilute hydrochloric acid and were analysed for copper by the solvent extraction-colorimetric method described by Wilson<sup>1</sup>. The random error of the solubility values reported is about  $\pm 5$  per cent, but this excludes the systematic error resulting from the deposition of copper in the sampling system. It has been shown, however, that deposition was only significant at the highest solubility values, above 400  $\mu$ g copper/kg. No dependence of solubility on the rate of flow through the autoclave was found at rates from 1–12 kg water per hour, indicating that solutions leaving the autoclave were saturated.

Pocock and Stewart<sup>2</sup> have also measured the solubility of copper, cuprous and cupric oxides in water in the temperature range 480°–620° C, but their results are almost an order of magnitude lower than those presented here. It is suggested that this discrepancy may result from:

Fig. 1. Isobaric solubility of cupric oxide and silica in water. ●, Present results with cupric oxide at 310 bars; Δ, Heitmann's results<sup>3</sup> with silica at 300 bars.

(a) incomplete acid cleaning of their sampling system; (b) insufficient equilibration time in the solubility autoclave; (c) interaction with the high concentrations of iron in the water, which resulted from their use of stainless steel equipment; (d) interaction with the hydrogen evolved during the corrosion of the stainless steel system.

The isobaric solubility of cupric oxide in water (pH 7.5) at 310 bars obtained in the present work is shown in Fig. 1, which also shows the 300 bar isobar for the silica (quartz) water system<sup>3</sup>. The two curves show a markedly similar variation of solubility with temperature, with the silica solubilities about three orders of magnitude greater than those of cupric oxide. This similarity suggests that the nature of the solvent determines the isobaric temperature coefficient of solubility for systems of this type, while the nature of the solute determines the absolute solubility level. It follows therefore that a generalized solubility equation based on the physical properties of the solvent is feasible. Attempts to formulate such an equation, for example by Martynova<sup>4</sup>, have included only the specific volume of the solvent and have not successfully correlated the experimental data for any given system. Work is in progress in this laboratory on an empirical equation which includes further physical properties of water.

### Solid State Polymerization at {00.1} Sub-grain Boundaries of Trioxane

THE polymerization of crystalline organic compounds in the solid state is an intriguing process, not least because of the influence of the crystal lattice. A recent review<sup>1</sup> distinguishes two chief categories depending on whether or not the resulting polymer bears a crystallographically defined relationship to the monomer crystal. In a preliminary investigation of this problem, microscopic observations have been made on the most frequently studied system, the polymerization of trioxane ( $\text{CH}_2\text{O}$ )<sub>3</sub> to polyoxymethylene [ $-\text{CH}_2\text{O}-$ ]<sub>n</sub>.

The evidence in the literature appears to be conflicting. On one hand, this process is the example par excellence in which polymer crystals are ordered with respect to the monomer<sup>1</sup>—a view based on X-ray evidence<sup>2</sup> from crystals polymerized to maximum yield and supported by observations of polymer fibres parallel to the trioxane *c* axis. But even here there is an apparent contradiction in that X-rays indicate two twinned orientations of polymer<sup>3</sup>, a conclusion not entirely supported by polarizing microscopy<sup>4</sup>. On the other hand, microscopy of the initial polymer showing assorted fibre directions within one grain and also straight fibres passing through several grains seems to indicate that, in detail, there is in fact no well defined orientational relationship between monomer and polymer crystals. The present experiments not only offer a possible reconciliation between these earlier observations because morphologies similar to both have been observed in distinguishable circumstances, but also they identify, for what is believed to be the first time, the preferred site of polymerization as a particular element of crystal sub-structure—{00.1} sub-grain boundaries in trioxane.

The experimental procedure used differs from established procedures only in having a higher dose rate during irradiation. Thin, melt-grown crystals of trioxane, 40–80  $\mu$  thick, prepared from previously sublimed trioxane and sealed between microscope slide and cover glass were irradiated with a standard dose of 1 MeV electrons ( $2 \times 10^{13}$  electrons/cm<sup>2</sup> incident over 10 sec). In all cases the trioxane *c* axes lay in the surface of slide. Specimens were then heated at 55°C for varying intervals before being quenched to room temperature for polarizing microscopy. Reheating was ineffectual in producing further polymer. It was also possible to examine the polymer in the electron microscope after pumping off residual trioxane.

Fig. 1. Branching, fibrous polyoxymethylene formed on the slide-trioxane interface after irradiation. Crossed polars.

Fig. 2. Polyoxymethylene fibres showing the grain structure of the original trioxane subsequently pumped off. Crossed polars.

Polymer was observed to form in three distinct ways, two before heating to 55°C and one after. In all cases the polymer eventually formed fibrous crystals with *c* along the axis. The first occurrence, which is interesting in that it alone resembles the morphology cited against initially ordered polymer<sup>3</sup>, was as fibrous sheaves often at the junction of, and passing into, several grains of trioxane which appeared to have nucleated on it. This was infrequently observed and is believed to have been present in the trioxane before melting and recrystallization. Because these processes are likely to have disrupted earlier morphologies it does not necessarily indicate here a disordered relationship between monomer and polymer when first formed.

The second type of polymer appeared in small amounts on the slide-trioxane interface, independently of the direction of electron incidence. Very little (<1 per cent) was detected on the cover glass-trioxane interface. Fig. 1 shows an extreme case of the fibrous, branching, incipiently spherulitic morphology, which has no preferred orientation to the underlying trioxane. The habit is suggestive<sup>6</sup> of an origin in a surface diffusion process connected with local heating of the slide during irradiation. Certainly reduced dose rates (which should reduce heating) reduced the amount of polymer.

The third morphology is the important one which gives the high conversion of trioxane to polyoxymethylene. It occurs entirely systematically in crystal interiors after heating at 55°C beyond an induction time of about 10 min. Fibres grow in length along the *c* axis to the limit of the surrounding grain (Fig. 2). In every grain the reaction starts in the interior even though adjacent grains may have undergone maximum conversion to polyoxymethylene. Of special interest is that in all but a few per cent of cases polymer appears first at sub-grain boundaries, but only those in or near to {00.1}. None has been seen in the frequent {*hk*.0} sub-grain boundaries. Fig. 3 shows fibres growing out along *c* from such boundaries; adjacent areas are full of fibres. As first detected the polymer is a birefringent haze<sup>4</sup> which eventually becomes evidently fibrous. At all stages, however, the polymer is aligned with the trioxane, because both extinguish between crossed polars, with their common *c* axes parallel to one polar. Even when trioxane has been pumped off, to avoid ambiguity of interpretation due to its birefringence, there is no evidence in the polyoxymethylene of a second, twinned orientation. This is not necessarily incompatible with X-ray work, however, because the decrease of volume on polymeriza-

tion to which the twinning has been attributed<sup>3</sup> is, under these conditions, taken up by forming cavities at the outer surfaces.

After pumping off trioxane, before electron microscopy, the initial polymer appears as birefringent microcrystals concentrated along {00.1} sub-grain boundaries, although inevitably orientations are disturbed by the pumping. The tiny microcrystals are, initially, thin hexagonal platelets which ultimately join to form hexagonal, prismatic fibres. A few microcrystals together with fibres of a wide range of lengths are seen in Fig. 4, which also illustrates the general observation that lateral dimensions vary little. It is tempting to attribute these dimensions to the microstructure of the sub-grain boundaries, but this factor has still to be investigated.

Fig. 3. Polyoxymethylene forming at {00.1} sub-grain boundaries (A) and extending along the c axis of the host trioxane crystal. Note also the pre-fibrous "haze" at B. Crossed polars.

Fig. 4. Hexagonal platelets and prismatic fibres of polyoxymethylene polymerized from trioxane. Electron micrograph.

The importance of crystal sub-structure to solid state polymerization has been suggested in the past to account for the sensitivity of reaction rates to crystal size (see, for example, ref. 1) and to pressure<sup>7</sup>. In acrylamide, which like the other examples forms a glassy polymer, the observation that initial polymer appeared along lines<sup>8</sup> (the precise nature of which was not identified) has been interpreted to mean that dislocations are necessary for the disruption of lattice regularity to allow polymerization to proceed<sup>1</sup>. In contrast, for trioxane, which cannot be polymerized while liquid, it is supposed that lattice perfection favours reaction. These conclusions need modification in view of the experiments reported here, which reveal that in trioxane reaction can occur preferentially at certain defect structures. It would seem reasonable to look for the origins of this here, as in many inorganic systems, in enhanced diffusion along and stresses associated with defects<sup>9</sup>.

## Photochemical Oxidation of Neptunium(V) by Xenon Trioxide

XENON trioxide is a strong oxidizing agent, with a potential of  $-1.8$  V (ref. 1) and the kinetics of several of its oxidation reactions, all of them thermal, have been studied<sup>2-4</sup>. We have now obtained evidence of a photochemical reaction in the course of a study of the oxidation of neptunium(V) by xenon trioxide

The neptunium(V) solution was prepared by dissolving neptunium dioxide in concentrated perchloric acid and reduction of the resulting neptunium(VI) to neptunium(V) with hydrogen peroxide. After standing for about 2 weeks, the solution was heated in a boiling water bath to destroy any peroxide present. The ionic strength was maintained constant at 2 molar with lithium perchlorate and recrystallized six times before use. The xenon trioxide solution had been passed through a zirconium oxide-zirconium phosphate bed to remove fluoride. It was standardized by reduction with excess potassium iodide and then by titration of the iodine produced with standard sodium thiosulphate.

The reaction was conducted in the light path of a Cary model 14 recording spectrophotometer, using a water-jacketed 1 cm spectrophotometer cell through which water at a known temperature was passed. All the runs were conducted at 60° C, to ensure that the reaction occurred at a rate which could be conveniently measured. The light source of the spectrophotometer, a tungsten filament projection lamp, was kept on during each run and the solutions were exposed to its full spectrum of light because in the infra-red mode the light passed through the sample before going through the monochromator. The concentration of neptunium(V) was followed at 980 mμ (neptunium(V) molar extinction coefficient 395 l.mole<sup>-1</sup> cm<sup>-1</sup>; neptunium(VI) molar extinction coefficient nil<sup>5</sup>). The several steps of data reduction were accomplished by

means of a computer programme\*. Reduction of the absorbancy readings yielded neptunium(V) concentrations from which xenon trioxide concentrations were calculated using the reaction stoichiometry and the initial xenon trioxide concentrations. Finally, values of  $k$  were obtained by substituting the values of these concentrations and their associated time co-ordinates into the integrated forms of various explicit rate expressions. It was concluded that the reaction rate is first-order in xenon trioxide and zero-order in neptunium(V) because of the relative constancy of the  $k$  values obtained from the corresponding integrated rate expression. Plots of values of the right-hand side of the integrated first-order rate equation

$$k_1 t = \frac{6 \ln [\text{XeO}_3]_0}{[\text{XeO}_3]}$$

versus time yielded straight lines, the slopes of which were equal to  $k_1$ . The least-squares values of  $k_1$  obtained in this manner (Table 1) confirm that the reaction follows the rate expression

$$-d[\text{Np(V)}]/dt = k_1 [\text{XeO}_3]$$

The rate also appears to be independent of acidity in the 0.5–2 molar acid range.

Table 1. FIRST-ORDER RATE CONSTANTS\*

0.002073	0.001940	2	12	4.87 ± 0.03
Average				6.28 ± 0.58

\* Because this is a photochemical reaction and the ultra-violet light flux was not known, the numerical values of  $k_1$  have no real significance. They are included to demonstrate the constancy of  $k_1$  under the conditions of these experiments.

† Uncertainties are standard deviations. In computing the standard deviation of the average, the standard deviations of individual runs were disregarded, because they are small compared with the variation of  $k$  between runs.

The reaction observed appears to be a photochemical reaction caused by absorption of ultra-violet light by the xenon trioxide

The formation of the excited species is the rate-controlling step in the reaction; once formed, this species reacts relatively rapidly with neptunium(V). Such a photochemical reaction is consistent with the high molar extinction coefficient of xenon trioxide at wavelengths below 300 mμ (in acid solution  $\epsilon \sim 50$  at 290 mμ;  $\epsilon \sim 100$  at 280 mμ<sup>1</sup>), the emissivity spectrum of the spectrophotometer lamp, and the transmittance of the spectrophotometer cell walls at these wavelengths.

Other runs at 60° C, conducted outside the spectrophotometer light path, did not obey the rate law given here; the reaction was much slower and exhibited non-integral dependence on the neptunium(V), xenon trioxide, and possibly also the neptunium(VI) concentrations. The slowness and complexity of this thermal reaction tend to support the hypothesis<sup>4</sup> that xenon trioxide preferentially oxidizes by a two electron change mechanism, and that the reaction is hindered in cases—such as the present one—in which only a one electron change is permissible. It would be premature, however, to draw a definite conclusion from these limited data.

We thank the Chemistry Division of Argonne National Laboratory for the xenon trioxide used in this study. We also thank Mr P. G. Hagan for experimental assistance

and Professor Edward L. King for many helpful suggestions. This work was performed under contract with the US Atomic Energy Commission.

### Photo-oxidation of Magnesium Porphyrins and Formation of Protobiliviolin

As part of a series of experiments on the photo-oxidation of vinylporphyrins<sup>1</sup>, I have studied complexes of protoporphyrin dimethyl ester with various transition metals. Non-fluorescent complexes of protoporphyrin dimethyl ester with iron, nickel, cobalt, copper and silver underwent no alteration in their spectral and chromatographic properties when they were irradiated in benzene with the light of a 500 W lamp. Complexes of lead with the protoporphyrin ester dissociated more rapidly under this treatment than the corresponding cadmium compounds. Zinc protoporphyrin slowly photo-oxidized to a brown unidentified compound.

Magnesium protoporphyrin ester (I) similarly irradiated in benzene, toluene, cyclohexane or chloroform photo-oxidized rapidly to give a greenish brown solution. By chromatography on a column of micro-crystalline cellulose thoroughly preflushed with nitrogen, using mixtures of benzene and light petroleum for elution, a green pigment was obtained. This green pigment contained no magnesium and was very labile: subsequent chromatography on cellulose caused it to decompose to give a biliviolin (II). The green pigment could be stored in deoxygenated benzene at 4° C for several weeks with only slight decomposition, but if frozen at -16° C a biliviolin was obtained overnight.

The green photo-compound also converted to biliviolin when shaken in a benzene or ether solution with normal hydrochloric acid or ammonium hydroxide. Weak organic bases, such as pyridine, α- or β-picoline, or lutidine, slowly converted the pigment to biliviolin. The addition of copper or zinc acetate to benzene solutions of the photo-compound rapidly gave the corresponding metal-complex of biliviolin. The carbonyl reagents, hydroxylamine and potassium borohydride, also reacted with the pigment to give the biliviolin. Identification of the biliviolin as protobiliviolin (divinylbiliviolin), a new compound, was based on a comparison of its spectral properties and those of the hydrochloride and zinc complex, which fluoresced red under ultra-violet light, with the spectra of mesobiliviolin. The spectral shift expected for the replacement of two ethyl side chains by two vinyls was observed. Whether this protobiliviolin is only of IXα structure or is a mixture of isomers<sup>2</sup> is being investigated. Oxidation of the protobiliviolin in methanolic hydrochloric acid with ferric chloride gave a verdin identical with an authentic sample of biliverdin.

The visible spectrum of the green photo-compound in neutral solvents (Fig. 1) connotes an extended series of double bonds, and low extinction ( $10^{-3} \epsilon = 26$  at 426 mμ) in the near ultra-violet is evidence that the ring conjugation of the porphyrin has been interrupted. Moreover, the characteristic fluorescence of the porphyrin is absent. Infra-red spectra of the green photo-compound

Fig. 1. Spectra of protohydroxyoxophlorin in benzene (—); urophlorin<sup>3</sup> in water at pH 6.8 (---).

in carbon tetrachloride showed a strong band at  $1,680\text{ cm}^{-1}$ ; as the pigment decomposed this band disappeared, to be replaced by a band at  $1,706\text{ cm}^{-1}$  due to the keto-amide carbonyl groups of biliviolin. From this spectral evidence and the reactivity of the green compound towards hydroxylamine and potassium borohydride, it is concluded that one of the methene carbons has been oxidized to a carbonyl. Because magnesium porphyrins without vinyl side chains photo-oxidize to similar green compounds (Table I) with a band at  $1,680\text{ cm}^{-1}$ , this band is evidently not due to the oxidation of a vinyl side chain.

The visible spectra of these green compounds are remarkably similar to those of the phlorins<sup>3</sup> (dihydro-

Table I. MAXIMA OF ABSORPTION OF HYDROXYOXOPHORINS AND PHLORINS ( $\lambda$  in  $m\mu$ )

porphyrins having one methine bridge hydrogenated). The spectra of both compounds in the near ultra-violet region show satellite bands to the principal bands and the positions of maxima of absorption are very similar (Table I). The two maxima observed in the band, in the far red of the photo-product of magnesium protoporphyrin, can be ascribed to the asymmetry of the electron field induced by the keto-group. Furthermore, the green pigment is converted to a blue green form, with  $\lambda_{\text{max}}$   $660\text{ m}\mu$  at pH 9.0 (which rapidly decomposes to proto-biliviolin). Urophlorin undergoes a similar spectral transition above pH 9.2. The lability of the green compound has prevented direct analysis of the number of oxygen atoms added to the tetrapyrroles during photo-oxidation. Structure III, or a methene isomer, however, accounts for present spectral and chemical evidence and would explain the instability of the molecule. Libowitzky *et al.* have prepared from natural porphyrins<sup>4</sup>, and Jackson *et al.* have synthesized<sup>5</sup>, oxyporphyrins which have one methine carbon similarly oxidized, but instead of the hydroxyl at the  $\alpha$ -pyrrolic carbon they have an extra hydrogen on a  $\beta$ -pyrrolic carbon or a nitrogen, and thus retain conjugation of the ring system. These oxyporphyrins, their cations and metal complexes are considerably more stable than the hydroxyoxophlorins and can be transformed to porphyrins. Compounds of the class of structure III will be referred to as hydroxyoxophlorins.

I

II

III

IV

The photo-oxidation of a methene carbon of a magnesium porphyrin is dependent on the electron distribution on the methene bridge carbon. The corresponding hydroxyoxophlorins were obtained by irradiating magnesium deuteroporphyrin and magnesium mesoporphyrin esters. Magnesium monoformyldeuteroporphyrin, magnesium porphyrin *a* esters and magnesium chlorins were not photo-oxidized. An additional factor is the stability of the metal porphyrin bond. In a series of magnesium porphyrins photo-irradiated in benzene, the stability of the metal porphyrin bond paralleled the thermodynamic stability<sup>6</sup> of these complexes. From magnesium-deuteroporphyrin only a trace of free porphyrin was found, but significant amounts of protoporphyrin were obtained from magnesium protoporphyrin, and magnesium dissociated even more rapidly from magnesium monoformyldeuteroporphyrin, magnesium porphyrin *a*, magnesium monovinyl- and magnesium monovinylmonocarbonyl-chlorin.

A strongly electron donating ligand completely suppresses the formation of hydroxyoxophlorins. Magnesium deuteroporphyrin and magnesium mesoporphyrin dipyrindino-complexes in benzene could not be photo-oxidized. A similar effect was obtained with  $\beta$ -picoline, but not with  $\alpha$ -picoline or lutidine. With the dipyrindino-complexes of magnesium protoporphyrin and of magnesium monovinylmonohydroxyethyl deuteroporphyrin, however, photo-oxidation occurred, not at the methene bridge but on one of the pyrroles at the vinyl side chain to give magnesium dioxyporphyrin and magnesium dioxymonovinylmonohydroxyethyldeuteroporphyrin. Free dioxyporphyrin (IV) (ref. 1) is obtained on photo-oxidation of protoporphyrin in either benzene or pyridine. Complexing of the magnesium porphyrins with pyridine or picoline had the further effect of stabilizing the magnesium-porphyrin bond. The pyridine complex of magnesium diformyldeuteroporphyrin and magnesium porphyrin *a* could be photo-irradiated for long periods without dissociation of magnesium.

Only hydrophobic solvents permit the formation of hydroxyoxophlorins. None could be obtained when magnesium protoporphyrin was irradiated in alcohols, ketones or were dispersed in 'Emasol' phosphate buffer at pH 6.8. In either neither photo-oxidation of the porphyrins nor dissociation of the magnesium occurred.

The photo-oxidation of magnesium porphyrins, to give specifically biliverdins on splitting of the ring, contrasts with the biliverdin obtained, which has three methene bridges, as the product of the opening of the porphyrin ring on chemical oxidation of pyridine haemochromes. The transformation of oxophlorin to biliverdin requires not only the addition of oxygen, because the methene carbon probably leaves as CO, or CHO, but also a reduction. Moreover, the photo-oxidation of the disodium complex of aetioporphylin in pyridine<sup>7</sup> gave a mixture of verdins and violinoid pigments.

The specific formation of protobiliverdin from magnesium protoporphyrin raises the possibility that magnesium protoporphyrin is a precursor of the chromophores of *c*-phycoerythrin and *allo*-phycoerythrin, and possibly the chromophore of phytochrome. The absorption spectrum of magnesium protoporphyrin is very close to the photo-action spectra of the formation of phycoerythrin<sup>8</sup>.

Magnesium protoporphyrin has been implicated as a precursor<sup>9</sup> of chlorophyll, and the cell membrane could provide a hydrophobic environment, required for the formation of the oxophlorin.

I have now found<sup>10</sup> that at least one vinyl group appears to be present in the native chromophore attached to the protein, and the other vinyl present in the protobiliverdin could be involved in a covalent linkage to the protein.

The spectral shift observed (725–665 m $\mu$ ) for phytochrome on going from the enzymatically active forms, Pfr, to the inactive form, Pr, closely mimics that found for hydroxyoxophlorins on going from neutral to alkaline

solvents. This strongly suggests that the chromophore is not of the biliverdin type<sup>11</sup>, but still has a bridge carbon present.

## MOLECULAR STRUCTURE

### Nucleotide Sequence of 5S-ribosomal RNA from *Escherichia coli*

In 1964 Rosset, Monier and Julien<sup>1</sup> described and characterized a low molecular weight ribonucleic acid (5S RNA) that is present in the ribosomes of *Escherichia coli* in addition to the two larger components, the 16S and 23S RNA. It contains 120 nucleotide residues and in contrast to transfer RNA contains no "minor" bases. Using a two-dimensional fractionation procedure for the separation of nucleotides labelled with phosphorus-32 (ref. 2), we have determined the sequences of all the oligonucleotides obtained by complete digestion of <sup>32</sup>P-labelled 5S RNA with ribonuclease T1 and ribonuclease A (pancreatic ribonuclease)<sup>3</sup>. In order to arrange these nucleotides in the unique sequence of the 5S RNA, we

Fig. 1. Sequence of the two chief 5S RNAs of *E. coli* (MRE600) showing regions involved in base-pairing. A solid line indicates a "standard" (G—C or A—U) pair and a dashed line a G—U pair, for example, between residues 81 and 95.

## BIOPHYSICS

## Electron Spin Resonance in Biological Tissues

SEVERAL points arise from the recent communication by Dettmer, Driscoll, Wallace and Neaves<sup>1</sup>.

First, the simple factors affecting electron spin resonance signals in tissues, which they set out to describe, seem to be only the rapid decay of free radical signals, as measured extensively by Commoner and Ternberg<sup>2</sup>, Kerkut *et al.*<sup>3</sup> and mentioned briefly as a source of error by Mallard and Kent<sup>4</sup>. Far from not having appeared in print, as stated in their first paragraph, it is seen that many workers have noted this effect.

Second, the techniques of lyophilization used by Dettmer *et al.* seem to us to be unnecessary and, in certain respects, dangerous. It was shown by Truby *et al.*<sup>5</sup> that lyophilization can create unwanted free radicals in organic materials, and Varian Associates, Inc., even show an example of this in their literature. We think that it is unnecessary to use this technique because adequate techniques now exist for the study of whole tissues at both room temperature and low temperatures<sup>2-4</sup>.

That lyophilization has some effect can be shown from the spectra of lyophilized samples which Dettmer *et al.* show in their communication. These spectra, when observed in the light of the methods of analysis of Searle *et al.*<sup>6</sup> and Lebedev<sup>7</sup>, are seen to represent asymmetric lines, possibly arising from *g*-value anisotropy. The lines have a Lorentzian shape and the anisotropic splitting in terms of individual line width is about 3.0.

On the other hand, the lines observed by other workers, although still asymmetric, can be shown to have a value of anisotropic splitting approximately equal to 2.0, which applies both at room and low temperatures down to 77° K. In addition, the spectra under these conditions result from individual lines of Gaussian shape. Because these Gaussian spectra are in the presence of water (and therefore an environment containing many protons) the Gaussian shape may result from the broadening effect of

have now studied the products of various partial ribonuclease digestions. This has involved the development of a number of new techniques which will be described in detail later. From the large number of partial digestion products obtained, we deduced the unique sequence shown in Figs. 1 and 2.

Fig. 1 is drawn to show the residues which are believed to be involved in base-pairing. These base-paired regions were identified as four sequences which were particularly resistant to digestion by ribonucleases. The longest double-stranded region is believed to be formed by base-pairing between the two ends of the molecule, and there are also two smaller "loops". Base-pairing between the two ends of the molecule is also found in transfer RNA, but otherwise there is less base-pairing in 5S RNA than in transfer RNA.

It will be noted that two residues are shown as occupying position 13. It appears that there are two 5S RNAs, presumably controlled by separate genes, one having a G in position 13 and the other a U. This was found in one strain of *E. coli* (MRE600, obtained from Dr H. E. Wade of the MRE Experimental Station, Porton, Wiltshire), while in another strain (CA265, obtained from Dr S. Brenner of this laboratory) a difference has been found in another position. It is probable that there are also other minor heterogeneities and therefore Fig. 1 illustrates the structure only of the two principal components of 5S RNA in *E. coli*, MRE600.

There are two sequences of ten and eight residues, respectively, that are repeated twice in the molecule. In Fig. 2 the structure is written so that the common sequences are aligned. There is considerable homology between the two parts of the chain, indicated by the boxed regions. This observation suggests that the 5S RNA may have evolved from a smaller RNA by a duplication of a part of the DNA sequence within the gene. There also appears to be some homology between the two ends of the molecule as shown by the underlining in Fig. 2. This could be explained by a separate duplication.

Fig. 2. Homologies between the two halves of the sequence of 5S RNA. The residues are numbered as in Fig. 1. Homologies are shown by the boxed areas. Dashes are where gaps have to be left in the sequence in order to maximize these homologies. The underlining shows similarities between the two ends of the molecule.

Previous work on RNA sequences has been confined to transfer RNAs and a number of complete sequences have been reported<sup>4-7</sup>. The 5S RNA is 120 residues long compared with 75-85 residues in the transfer RNAs, and the absence of "minor" bases makes interpretation somewhat more difficult. This work shows, however, that it is possible, using the small-scale techniques which we have developed, to determine the nucleotide sequence of an RNA labelled with phosphorus-32.

this. The difference in the apparent anisotropic splitting between the Lorentzian and the Gaussian spectra may arise from a difference in individual line width between the two cases. Because no details of line widths are published by Dettmer *et al.*, however, it is not possible to follow this further.

Alternatively, it is possible that the differences described here arise merely because these authors are observing electron spin resonance signals generated by the lyophilization process, and this in itself represents a serious pitfall.

## IMMUNOLOGY

## Rapid Activation of Lymphocytes by Phytohaemagglutinin

WHEN human small lymphocytes are incubated *in vitro* with phytohaemagglutinin (PHA) a large proportion of them transform into large, rapidly dividing lymphoblasts<sup>1</sup>. Synthesis of DNA begins about 24 h after the addition of PHA<sup>2</sup>. Nowell<sup>1</sup> and Newsome<sup>3</sup> found that when lymphocytes were in contact with PHA for 1 h or less a lesser degree of transformation took place, and preliminary results in this laboratory suggest that exposure of lymphocytes to PHA for 3 h results in substantial transformation<sup>4</sup>, as judged by the incorporation of <sup>14</sup>C amino-acids into protein. This finding has been re-investigated in the light of recent reports that little transformation or synthesis of DNA occurs if the period of exposure to PHA is less than 24 h (refs. 5-7).

Lymphocyte cultures were prepared and incubated as previously described<sup>1</sup>. After incubation of cultures for the time required, medium containing either tritiated thymidine (3.3  $\mu$ Ci/ml.) or <sup>14</sup>C leucine (1  $\mu$ Ci/ml.) was added and isotope incorporation was determined after incubation of the cultures for a further 2 h. Two preparations of PHA have been used in these experiments, PHA-W (Burroughs Wellcome) and PHA-P (Difco). PHA-W was used at a final concentration of 150  $\mu$ g/ml., and PHA-P at 25  $\mu$ g/ml. These concentrations were found to cause the greatest stimulation of the incorporation of tritiated thymidine and <sup>14</sup>C leucine in lymphocyte cultures incubated with PHA for 30 or 48 h.

Fig. 1 shows that cultures incubated without PHA incorporate little tritiated thymidine. Both preparations of PHA caused a marked stimulation of the incorporation of tritiated thymidine, beginning about 24 h after the addition of PHA. These results are similar to those found by other workers<sup>2</sup>. At all times from 27 to 70 h after the addition of PHA, PHA-W caused more incorporation of tritiated thymidine than PHA-P. In several experiments, it was shown that this result was not due to the use of sub-optimum concentrations of PHA-P. PHA-W was also more effective than PHA-P in stimulating the incorporation of <sup>14</sup>C leucine.

When lymphocytes were incubated with PHA-W for 1 h and then the PHA removed, the rate of incorporation of tritiated thymidine after incubation for 48 h was about 50 per cent of that found when PHA was present throughout the incubation (Fig. 2). When the time of incubation with PHA was increased to 3 h, incorporation of tritiated

Fig. 1. Incorporation of tritiated thymidine. Cultures were incubated with or without PHA and at the times indicated the medium was replaced by medium containing tritiated thymidine (3.3  $\mu$ Ci/ml.). The incorporation of tritiated thymidine was determined after incubation for a further 2 h. ●, PHA-W; ○, PHA-P; ×, no PHA.

Fig. 2. Effect of limited exposure to PHA on the incorporation of tritiated thymidine. Cultures were incubated with PHA for the times indicated and culture medium was removed after gentle centrifugation. The cells were washed once with culture medium and then resuspended in medium either with or without additional PHA. After incubation of cultures for a total of 48 h the incorporation of tritiated thymidine during a 2 h period was determined. The incorporation found after incubation with PHA for a limited period is expressed as a percentage of the incorporation by cultures incubated with PHA throughout. ●, PHA-W; ○, PHA-P.

thymidine was 70-90 per cent of control levels, and after incubation with PHA-W for 8 h further addition of PHA did not lead to any significant increase in the incorporation of tritiated thymidine. Fig. 2 shows that a longer incubation with PHA-P was required for maximal stimulation of tritiated thymidine incorporation to result, but even when the exposure to PHA-P was for 1 h the incorporation of tritiated thymidine was substantially higher than that found in cultures incubated without PHA. Increasing the concentration of PHA-P to 50  $\mu$ g/ml. did not affect the results, and in all cases the results obtained when the incorporation of <sup>14</sup>C leucine was investigated were similar to those found with tritiated thymidine.

The possibility that PHA might be taken up and later released by phagocytic cells contaminating the cultures was excluded because similar results were obtained when cultures of nearly pure lymphocytes, prepared by the cotton wool column method<sup>8</sup>, were used. To exclude the possibilities that PHA was not removed by the washing procedure, or that it was bound to the red blood cells or to the culture vessels, red blood cells were incubated with and without PHA for 3 h, and after the removal of the PHA the red blood cells were washed and unstimulated lymphocytes added. The incorporation of tritiated thymidine after incubation of the lymphocytes for 48 h was very low whether the red blood cells had been incubated with or without PHA. The red blood cells did not inhibit the incorporation of tritiated thymidine when PHA was added together with the lymphocytes.

The reason for the difference between the results reported here and those of Tormey and Mueller<sup>6</sup> and Yamamoto<sup>6</sup> is not obvious. The washing procedures used by these authors do not appear to be more rigorous than ours. It may be relevant that these authors used a preparation of PHA not used in these studies, PHA-M (Difco), but PHA-M was also used by Newsome<sup>3</sup>, who found some transformation after incubation of lymphocytes with PHA for short periods. The experiments reported here are not necessarily comparable with those of Mellman and Rawnsley<sup>7</sup>. These workers also used PHA-M, but the PHA was inactivated by the addition of antibodies. It is possible that PHA could be bound to the cells in such a way that it was not removable by washing, but was accessible to neutralizing antibodies.

Ling and Holt<sup>9</sup> found that exposure of lymphocytes to a purified preparation of PHA-W for 16 h caused sub-

stantial transformation. Their results are in good agreement with those reported here. A similar purified preparation of PHA-W has been used in these experiments, and the results obtained did not differ significantly from those found with crude PHA-W except that the concentration of PHA-W causing maximal stimulation of incorporation of tritiated thymidine was reduced to 2.5  $\mu\text{g/ml}$ . The transformation of lymphocytes by antibodies to autologous gamma globulins has been shown to follow exposure of lymphocytes to the stimulant for less than 1 h (refs. 10 and 11).

The results reported here suggest that the period of exposure of lymphocytes to PHA required for transformation may be short. Comparison of these results with those obtained by other workers shows that the factors affecting the period required are not yet established, but suggest that they may include the preparation of PHA used. The results suggest that the active components of PHA-W and PHA-P may not be identical, and that the PHA-W preparation is the more active. An alternative explanation would be that the active components of the two PHA preparations were identical, but that the PHA-P preparation contained a substance that inhibited lymphocyte growth.

I thank Dr A. Korner and Dr D. R. Forsdyke for their interest in this work, the Medical Research Council for a research grant to Dr Korner, and the Science Research Council for a studentship.

### Release of Histamine and Slow Reacting Substance with Mast Cell Changes after Challenge of Human Lung sensitized passively with Reagin *in vitro*

I HAVE examined various tissues for their ability to adsorb reagins from whole serum *in vitro*, and human lung was one of the most effective adsorbents. I tested fresh human lung, removed at operation from a non-allergic individual, for passive sensitization, and release of histamine with mast cell changes after challenge with antigen *in vitro*.

Sera used to sensitize the lung fragments passively were from two patients, allergic to milk, who gave an immediate skin response to milk protein. The sera contained reagins to  $\beta$ -lactoglobulin detected by passive cutaneous anaphylaxis in baboons. Two sera, which contained similar agglutination titres of IgG and IgA antibodies to  $\beta$ -lactoglobulin, were from normal persons and two were from cases of cot death. The sera were tested for IgG, IgA and IgM antibodies to  $\beta$ -lactoglobulin by the very sensitive red cell linked-antigen antiglobulin reaction, employing monospecific antiglobulin sera<sup>1</sup>, and also for potency in preparing skin for passive cutaneous anaphylaxis in baboons, with 28 h between sensitization and challenge (Table 1). None of the sera sensitized guinea-pig skin for passive cutaneous anaphylaxis after a latent period of 4 h. Any release of smooth muscle contracting agents caused by soluble antigen-antibody complexes, although their formation in the test conditions

Table 1. RECIPROCAL OF SERUM ANTIBODY TITRES TO  $\beta$ -LACTOGLOBULIN BY THE RED CELL LINKED ANTIGLOBULIN TEST AND PASSIVE CUTANEOUS ANAPHYLAXIS IN BABOONS

Serum	Titres			Passive cutaneous anaphylaxis
	IgG	IgA	IgM	
Normal 1	32	4	0	0
Normal 2	128	32	2	0
Milk sensitive 1	64	16	0	32
Milk sensitive, heated	64	16	0	0
Milk sensitive 2	64	8	4	16
Cot death 1	128	16	32	0
Cot death 2	32	8	4	0

is unlikely, was controlled by testing in parallel sera from non-allergic and allergic individuals with agglutination titres very similar to the pure  $\beta$ -lactoglobulin.

Fresh lung was cut into sections 1–2 mm thick including fragments of pleura and small bronchioles, and divided into equal portions weighing 200 mg which were quickly enclosed in stainless steel mesh folded flat to expose a large surface of tissue when submerged in fluid. These were washed in Tyrode solution at 37° C for 20 min, drained of surplus fluid, and treated with 1 ml. of the undiluted test serum. The sera from the normal and allergic subjects were tested three times, but the amounts of the sera from the cases of cot death could sensitize only one piece of lung each. After incubation for 20 min at 37° C they were washed twice in warm Tyrode solution with gentle agitation for 20 min and then slowly irrigated three times with 50 ml. of Tyrode from a reservoir 25 cm above the vessel containing the lung to ensure the removal of unbound serum protein.

The lung was challenged by a modification of the method of Mongar and Schild<sup>2</sup>. Each piece was placed for 10 min in 6 ml. of warm, aerated Tyrode. This solution was removed and kept as the control release sample.  $\beta$ -Lactoglobulin (50  $\mu\text{g}$ ) in 6 ml. of Tyrode was added and removed after 10 min as the test release sample. The control and test release samples, and two pieces of lung each in 6 ml. of Tyrode were placed in a boiling water bath for 5 min and the fluids were assayed for histamine and slow reacting substance. Fragments of a third piece of lung were fixed in 10 per cent formalin, in 4 per cent lead subacetate in 10 per cent formalin and in Bouin's fixative to preserve the mast cells. The single cot death samples were used only for histamine assay on guinea-pig ileum in Tyrode containing  $2 \times 10^{-7}$  molar atropine. The results are presented in Table 2. Release of histamine from the piece of lung used for mast cell examination is not shown, because it closely resembled that of the other two pieces in each test.

Table 2. HISTAMINE EXPRESSED AS  $\mu\text{g}$  OF BASE/200 mg OF TISSUE, RELEASED ON CHALLENGE OF HUMAN LUNG PASSIVELY SENSITIZED *in vitro*, AND MAST CELL CHANGE

Serum	Release				Percentage release		Changed mast cells/total counted after challenge
	Con-trol	Chal-lenged	Residual	Total	Con-trol	Chal-lenged	
Normal 1	0.25	0.32	11.05	11.62	2.2	2.8	7/200
Normal 2	0.40	0.37	9.33	10.10	4.0	3.7	11/200
Milk sensitive 1	0.22	2.60	8.72	11.54	1.9	22.5	58/100
Milk sensitive, heated	0.23	0.26	11.11	11.60	2.0	2.2	8/200
Milk sensitive 2	0.24	2.28	9.06	11.58	2.1	19.7	62/150
Cot death 1	0.42	0.49	7.49	8.40	5.0	5.8	Not done
Cot death 2	0.46	0.43	7.14	8.03	5.7	5.4	Not done

Results of normal sera and milk sensitive sera are the mean of two tests.

About 20 per cent of the total extractable histamine was released by antigen from lung sensitized passively with sera from patients allergic to milk; heating the serum at 56° C for 30 min before the tests destroyed the sensitizing activity. The non-specific release of histamine by the cot death sera without addition of antigen may have been caused by post-mortem tissue breakdown products, because histones and possibly other tissue components will disrupt mast cells<sup>3,4</sup>, or it may have been caused by enzymes activated by anaphylaxis, if this was the cause of death. The anaphylactoid effect of soluble complexes is unlikely to have been the cause, because

gel plate precipitation detected no milk antigen in the cot death sera.

One of the normal sera released nearly twice as much histamine as the other in the control release solution, which was probably caused by the cytotoxic effect on tissues of serum from another donor. The cause may have been non-allergic, but, theoretically, could have resulted from incompatible blood group antibodies.

Both histamine and slow reacting substance are released from lungs of actively sensitized persons when tested with antigen *in vitro*<sup>5-7</sup>. Because slow reacting substance increases the amplitude of the contraction of guinea-pig ileum induced by histamine when both are present, four of the test solutions were also examined for slow reacting substance, using  $10^{-6}$  molar mepyramine maleate to inhibit the histamine.

No detectable slow reacting substance was released with the histamine leached from the tissue before the test (Table 3), but because no precautions were taken to prevent its loss by adsorption to proteins or glassware there may have been small amounts in the samples. The contractions of guinea-pig ileum were small and slow with the solutions obtained from lungs sensitized with reagin after challenge, so that the histamine equivalent is probably slightly larger than the true histamine content<sup>8</sup>. The samples from the portions of the lung treated with cot death sera caused weak contractions before and after challenge; as with the histamine released this may have been caused by post-mortem tissue breakdown products in the sera or by activated enzymes releasing the pharmacological agents from the lung.

Table 3. RELEASE OF SLOW REACTING SUBSTANCE FROM HUMAN LUNG PASSIVELY SENSITIZED AND CHALLENGED *in vitro* BY ANTIGEN

Test serum	Release	
	Control	Challenge
Normal serum 1	—	—
Milk sensitive 1	—	—
Same serum kept at 56° C for 30 min	—	—
Milk sensitive 2	—	+
Cot death 1	tr	tr
Cot death 2	tr	tr

—, Absent; tr, trace; +, present.

Tables 1 and 2 show that passive sensitizing ability of the serum is unrelated to the titre of the IgA antibody, which was also found in tests with several antigens by the passive cutaneous anaphylaxis technique in baboons and by Prausnitz Kustner tests in man (my unpublished work). Furthermore, the IgA titre was unaltered in sera kept at 56° C, confirming the findings of Coombs *et al.*<sup>1</sup>, although the tissue passive sensitizing activity was destroyed. Thus either the antigen-binding and cell-binding properties of the antibody molecule are not equally susceptible to heat, or, more likely, IgA is rarely, if ever, reaginic.

The changes in mast cells, stained with 0.5 per cent aqueous toluidine blue and cleared with butanol, resembled those described after *in vitro* challenge of mesentery taken after death from a person actively sensitized to egg-white<sup>8</sup>. There were fewer mast cells in the sensitized lung after challenge, and of those remaining (Table 2) some had shed their granules or had become vacuolated with aggregation of the granules within the cell membrane, and in a few the granules had lysed in the cytoplasm and the nucleus was pyknotic. These changes were evident in lung fixed by all three methods; but the granules were most distinct after fixation in lead subacetate. Changes in mast cells are a useful indication of allergic reactions when release of histamine is also measured, but it provides unreliable evidence of anaphylaxis in tissues which have undergone inflammation and been sampled some time after death because non-specific changes occur; although anaphylaxis-like changes in mast cells have been seen in five out of fourteen lungs after cot death<sup>9</sup>.

Fresh human lung can be passively sensitized *in vitro* with reagins to milk, and when challenged releases hist-

amine concurrently with damage to mast cells. Its use in this way provides an additional method for the investigation of human allergies and particularly for the study of milk sensitivity and its relation to cot death in infants<sup>9,10</sup>. The independence of reagin activity and IgA antibody is confirmed. Two cot death sera did not sensitize the lung passively but both induced a spontaneous release of histamine.

I thank Drs R. Aschaffenberg for the  $\beta$ -lactoglobulin and S. D. Roberts for the rabbit-anti-human IgA and Drs H. R. M. Johnson, A. W. Frankland and G. A. Sterling for sera, material and help. I thank Sir Ashley Miles for his advice.

## Sodium Transport and Specific Antiserum

THE cytotoxic effects of tissue specific antibodies have been studied *in vivo* under conditions of auto-immunity (induced or idiopathic) and *in vitro* using cells in tissue culture<sup>1</sup>. Although much is known about the histochemical and morphological changes induced by specific antibodies, very little is known of the effect of specific antibodies on the active transport mechanisms of the cell membrane. We have used the urinary bladder of the toad (*Bufo marinus*) to test the effect of antibodies on the active transport of sodium.

Antisera to the urinary bladder were obtained from rabbits injected with a homogenized preparation of bladder tissue. The washed urinary bladder was homogenized with 3 ml. of toad Ringer solution (115 mmolar NaCl; 2.5 mmolar KHCO<sub>3</sub>; 1.0 mmolar CaCl<sub>2</sub>) using a hand homogenizer, and the resulting homogenate was diluted to 10 ml. with Ringer solution. Rabbits were injected intravenously with 1 ml. of tissue homogenate on alternate days for a total of three injections. One week after the last injection the rabbits were bled and the sera collected. The antiserum to the toad bladder (TBA) and the control serum, normal rabbit serum (NRS), were dialysed against Ringer solution before being tested.

The bladder was removed and divided into its equal hemispheres. Each hemisphere was mounted between two conical compartments which were then filled with 10 ml. of Ringer solution and continuously aerated (Fig. 1). One hemisphere served as the experimental tissue and the other as the control. The active transport of sodium was measured by the short circuit current (SCC) method of Ussing and Zerahn<sup>2</sup>.

After the tissue had been mounted, it was allowed to equilibrate for 1 h. At 1 h the transmembrane potential was adjusted to zero and the SCC required to maintain the transmembrane potential at zero was recorded every 10 min for the next 60 min to establish the stability of the membrane and to discern whether the sodium transport was increasing or decreasing with time. The membrane in the experiment represented by Fig. 1b was stable and

without an upward or downward trend. At 61 min (that is, 121 min after the tissue was mounted) 1 ml. of normal rabbit serum (NRS) was added to both sides (mucosal and serosal) of the control membrane and to the mucosal side of the experimental membrane; 1 ml. of TBA was added to the serosal side of the experimental membrane. A decrease in the SCC was observed in both cases. The addition of antiserum produced a 24 per cent decrease at 70 min as compared with a 4-5 per cent decrease when NRS was added. The percentage decrease in the SCC of the control was calculated by averaging the SCC values observed during the 30 min immediately preceding the addition of serum (4 per cent decrease) and again by using the value at 60 min (7 per cent decrease).

The experiment was repeated eight times. In seven out of eight experiments the SCC decreased when TBA was added to the serosal side (in one case the SCC remained constant) while no effect was observed when NRS was added (in the one exception the SCC decreased slightly).

The data were normalized in subsequent experiments by the following procedure. First, all SCC measurements were expressed as a fraction by dividing each value by the 60 min SCC measurement. In Figs. 2 and 3 the normalized SCC is referred to as the relative short circuit current (RSCC). Because the RSCC seldom remained constant, a trend in the RSCC was derived from the measurements made at 30, 40, 50 and 60 min and projected into the subsequent time period (see dashed line, Fig. 2). The trend was then equated to 1 and individual RSCC plotted as fractions. It was thus possible to com-

Fig. 1. An experiment demonstrating the effect of specific antiserum on sodium transport. Reagents added to the mucosal (M) and serosal (S) chambers are indicated by schematic drawing of the urinary bladder mounted between the two conical chambers.

Fig. 2. Experiments demonstrating the effect of various reagents (that is, Ringer solution, normal rabbit serum, antiserum and antiserum plus complement) on sodium transport.

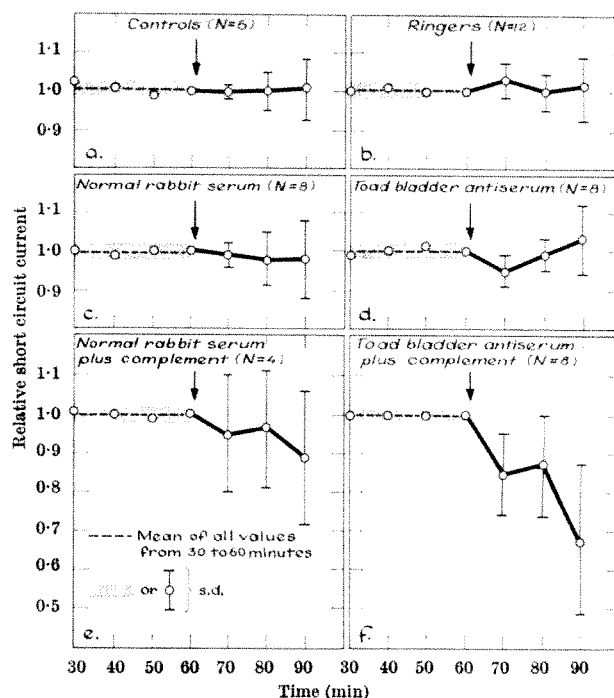

Fig. 3. Summary of combined results.

pare the results obtained from different membranes. Fig. 3 summarizes the results of forty-six experiments which were analysed by this procedure.

The results summarized by Fig. 3c and 3d are consistent with previous results. NRS had little or no effect on the RSCC and the addition of antiserum produced a significant decrease when added to the serosal side. The greatest decrease in the RSCC occurred at 70 min and it was followed by an upward trend, which was not observed in the NRS controls.

Because the decrease in SCC was small when antiserum was added, it was decided to test the system in the presence of complement to determine whether the response could be potentiated. At 61 min, 1 ml. of antiserum and 0.5 ml. of normal guinea-pig serum (complement) were added to both sides of the membrane. The 70 min measurement was 85 per cent of the value obtained at 60 min; at 90 min the RSCC had decreased to 55 per cent (Fig. 2d). In contrast to antiserum alone, the antiserum plus complement caused a dramatic and irreversible decrease in the RSCC (Fig. 3f).

The complement control experiments tested a combination of NRS and complement. This combination caused an average decrease in the RSCC of 5 per cent and caused a marked instability in the activity of the membrane as indicated by the large S.D. at 70 min (see Fig. 3d). The reaction elicited by the NRS complement combination might be because the normal guinea-pig serum was not dialysed against Ringer solution or because of the presence of heterophile antibodies in either or both sera.

The cytotoxic properties of specific antibodies have been extensively studied using mammalian cells in tissue culture. In the absence of complement, ascites tumour cells remain viable even in the presence of specific antibodies<sup>3</sup>. Changes are produced, however, by the antibody alone because in the presence of antibody the growth rate is slower than that of the controls, and if sufficient antibody is used death can occur<sup>3,4</sup>. Examination with the electron microscope of cells treated with ferritin labelled antibodies in the absence of complement revealed that antibodies were attached to the cell membrane and that the antibodies induced a labyrinthine folding of the membrane<sup>5,6</sup>. Thus even though the integrity of the cell

membrane was not destroyed by antibody alone, changes in the ultrastructure of the cell membrane were observed.

In view of work reported with mammalian cells we interpret our results in the following manner. Rabbits injected with toad bladder homogenates produced antibodies which specifically altered some part of the sodium transport mechanism. The small reversible decrease in the SCC elicited by antiserum alone could be explained by postulating that only a small percentage of the antibodies were directed to key transport structures on the cell membrane. The large irreversible effect produced by the addition of complement indicated that the integrity of the cell membrane was disrupted and all antibodies directed to the cell membrane were potential contributors towards its destruction. Thus antibodies specific for those parts of the membrane responsible for sodium transport caused the initial reversible decrease in SCC; antibodies directed to the membrane in general in the presence of complement caused irreversible damage to the cell membrane and a subsequent decrease in the SCC.

### Renal Transplantation in Cattle Twins

SIMONSEN<sup>1</sup> was the first to demonstrate that in one pair of chimeric cattle twins renal transplants produced urine for 5 months, and Calne<sup>2</sup> confirmed this observation. Recently, Cragle and Stone<sup>3</sup> reported that most of the renal grafts among chimeric cattle were still functioning at 76–295 days. These reports<sup>1–3</sup> did not contain details of histological and functional changes in the grafts. The present communication presents the results of histological study of renal transplants in 3–6 month old calves. Autografts, allografts between single born animals and grafts between non-identical twins were performed. The twins were from like-sexed pairs and were diagnosed as dizygotic by morphological criteria, for example, type and pattern of pigmentation and hair colour, shape of the head, general appearance and conformation. Blood typing was not done. Because of the high incidence (90 per cent) of chimerism in cattle twins<sup>4</sup>, however, it seems likely that these animals were chimeric.

The kidney, usually the left, was transplanted to the left side of the neck after perfusion with heparin and procaine containing cold (4°C) Hartmann solution. The vascular anastomoses were completed within 30 min and the ureter was anastomosed to the oesophagus. In each animal only one of its own kidneys was retained *in situ*. Percutaneous needle biopsies of the graft were taken at various times.

In biopsies from the four allografts, taken at daily intervals, there was progressive lymphocytic infiltration from day 3 onward indicating graft rejection. In three of the grafts there were also changes of superimposed pyelonephritis, that is, some of the tubules contained pus cells. All the grafts became necrotic between days 10 and 14. On removal, the arterial and uretero-oesophageal

anastomoses were patent but the renal veins contained fresh thrombi.

Biopsies were taken at 2, 3 and 4 weeks from the two autografts. The grafts were removed at 4 months. In one graft no pathological changes were observed. In the other autograft the biopsy taken at 2 weeks showed acute pyelonephritis which subsided during the following two weeks. On removal the kidney was scarred. Histologically there were wedge shaped areas of fibrosis in the cortex which contained a moderate lymphocytic infiltration. There were no changes indicating graft rejection. Samples of urine produced by the graft and *in situ* kidney were collected immediately before removal of the graft; both were free of protein and contained normal concentrations of sodium, potassium, chloride and urea.

From the four grafts between co-twins the biopsies obtained at 2, 4 and 8 weeks showed progressive lymphocytic infiltration, tubular degeneration and atrophy and thickening of blood vessels. In three grafts, there was also evidence of pyelonephritis. These three grafts were removed at 4 months. The fourth graft was excised at 8 months. In all grafts, except one removed at 4 months, the anastomoses were patent. In this graft the renal artery contained a recanalized thrombus and the uretero-oesophageal orifice was occluded by fibrous tissue. In the graft removed at 8 months there was marked perivascular and periglomerular infiltration with small lymphocytes, plasma cells and "large pyroninophilic cells", localized tubular atrophy and necrosis, periglomerular fibrosis, intimal and medial fibrosis of arteries and some veins (Fig. 1), massive periureteral lymphocytic infiltration sharply terminating at the uretero-oesophageal junction (Fig. 2), and ingrowth of muscular arteries from the renal capsule (Fig. 3). These observations suggest an immunologically mediated graft rejection process. Comparison of chemical analyses of urine samples from the graft and from the animal's own kidney, collected immediately before removal of the graft, showed that their concentrations of sodium and chloride were similar. The urine from the graft contained less potassium (44:130 m.equiv./l.) and urea (150:800 mg per cent) and more lactic acid dehydrogenase (242:29 U/ml.). Protein was present only in the urine from the graft (110 mg per cent).

Fig. 1. Co-twin renal graft at 8 months. Section of kidney showing massive lymphocytic infiltration, parenchymal damage and vascular thickening. (Haematoxylin and eosin,  $\times 42$ .)

In the other three co-twin grafts, the complicating infection had not affected all segments of the kidney. In the areas without suppuration, the histological changes were similar to those shown in Figs. 1-3.

The sequence of events and the histological findings in our allografts are similar to those described for immunological rejection of renal grafts in man and dog<sup>5,6</sup>. The time of rejection is similar to that described by Cragle and Stone<sup>3</sup> for cattle. Although all co-twin grafts survived for long periods of time, histological features associated with immunological rejection were already present in biopsies taken at 2 weeks. The rejection process progressed very slowly and in many respects resembled the changes that occur in allografts maintained by immuno-

Fig. 2. Same animal as Fig. 1. Section of uretero-oesophageal junction showing periureteral lymphocytic infiltration sharply terminating at the junction. (Haematoxylin and eosin,  $\times 17$ .)

Fig. 3. Same animal as Fig. 1. Section showing ingrowth of arteries from the renal capsule into the kidney. (Haematoxylin and eosin,  $\times 17$ .)

suppressive therapy<sup>7</sup>. The raised lactic acid dehydrogenase content of urine from the co-twin graft—a serious prognostic sign according to Prout *et al.*<sup>8</sup>—also indicates that the graft was being rejected. The slow mild rejection process in the kidney grafts which we observed is in agreement with findings of Billingham and Lampkin<sup>9</sup> and Stone *et al.*<sup>10</sup> on skin grafts between dizygotic cattle twins. The slow rejection of co-twin tissues and organs by chimeric cattle twins suggests that these animals are in a state of split tolerance<sup>11</sup>, that is, they are tolerant to only some of the antigens from each other. These experiments also help to explain the clinical observations that long term survival of renal allotransplants can occur when donor and recipient are unrelated but are largely compatible for principal erythrocyte and leucocyte antigens.

We thank B. M. White and other members of the S. S. Cameron Laboratory for help in obtaining the twin calves, and Professors R. C. Nairn and H. A. F. Dudley of the Departments of Pathology and Surgery, Monash University, for suggestions and criticism. The work was supported by the Australian Research Grants Committee and by the J. F. Mackeddie research scholarship and R. B. McComas medical research scholarship awarded by the Board of Management, Alfred Hospital, Melbourne, to one of us (J. N.).

### Concentration of Immunoglobulins in Lethally X-irradiated Mice

SEVERAL reports have been published concerning the immunoglobulins of sublethally and lethally irradiated mice<sup>1-4</sup>. These have relied on the techniques of electrophoresis and immunoelectrophoresis. The former, although it can yield some quantitative information, does not adequately distinguish between different classes of immunoglobulin, and the latter, while offering excellent resolution of immunoglobulin classes, is only in the roughest way quantitative. These studies have indicated that a profound drop occurs in the concentration of gamma-globulins within a few days after lethal irradiation. The availability of unispecific antisera to each of four mouse immunoglobulins<sup>5</sup>—IgA, IgM, IgG1 and IgG2a (ref. 6)—and the development of the technique of single radial diffusion in agar whereby such antisera can be used to yield quantitative measurements of their corresponding antigen<sup>7</sup> have now made it possible to obtain more precise information concerning the effects of radiation on the concentration of immunoglobulins.

Twenty male CBA/H mice, 5 months of age, were used. Seven received 1,000 rads (250 keV, 14 m.amp., half value thickness 1.2 mm copper), seven received 800 rads, and

the remaining six served as non-irradiated controls. Irradiation was administered ventro-dorsally to the whole body. The twenty mice were caged in four boxes, among which irradiated and control mice were distributed at random.

All mice were bled from the tail immediately before irradiation, and on the fifth, seventh and ninth days thereafter. Control mice were bled also on the twelfth, sixteenth and twenty-second days. The amount of blood taken on each occasion was about 0.05 ml.

Mortality among the irradiated mice was as follows:

	Time of death (days)
800 rads	8 (3 mice), 9, 10, 12
1,000 rads	6 (3 mice), 7, 8 (2 mice), 9

Each serum sample was individually titrated in single radial diffusion<sup>7</sup> against each of the four unispecific anti-Ig sera. Diffusion was allowed to continue for 14 days under paraffin oil, because shorter periods of diffusion had been found to give inconsistent results.

Pure reference preparations were made of IgM and IgG2a. IgM was prepared from normal mouse serum by separation of euglobulins on 'Sephadex G-25' (superfine grade), followed by filtration on 'G-200', as described elsewhere<sup>8</sup>; IgG2a was purified from paraprotein of mouse myeloma 5563 by the technique of Askonas<sup>9</sup>. Use of these reference preparations enabled us to express the results of titrations for IgM and IgG2a in mg protein/ml. of serum. No reference preparations of IgA and IgG1 were available, and the results are therefore related to a large pool of normal mouse serum the values for which are taken as unity.

There were no significant differences between the two irradiated groups in respect of any of the four immunoglobulins, and the results have therefore been pooled in order to simplify presentation and facilitate statistical comparison with the controls.

The concentrations of each of the four immunoglobulins in the serum are shown in Fig. 1. Each shows a progressive and significant fall in concentration from that before irradiation and this is most pronounced with IgA.

The percentage falls were as follows:

	IgM	IgA	IgG1	IgG2
Seventh day	11	86	41	56
Ninth day	32	85	68	56

The non-irradiated controls showed substantial fluctuations possibly due to the repeated bleeding; one consequence of this is that at no time can the concentrations of IgG1 and IgG2a in the experimental groups be shown to differ significantly from the controls of the same day. The statistical comparisons, based on Student's *t* test, are shown in Table 1.

Table 1. LEVELS OF SIGNIFICANCE, ESTIMATED BY STUDENT'S *t* TEST, OF THE DIFFERENCES IN THE CONCENTRATIONS OF Ig (A) BETWEEN IRRADIATED AND CONTROL MICE, AND (B) BETWEEN IRRADIATED MICE BEFORE AND AFTER EXPOSURE

	A Significance of difference from controls of same day			B Significance of difference from concentrations before irradiation		
	5 days after irradiation	7 days after irradiation	9 days after irradiation	5 days after irradiation	7 days after irradiation	9 days after irradiation
IgM	NS	<0.01	<0.01	<0.02	NS	<0.01
IgA	<0.05	<0.01	<0.01	<0.01	<0.01	<0.01
IgG1	NS	NS	NS	<0.05	<0.05	<0.01
IgG2	NS	NS	NS	NS	<0.02	<0.05

NS, Not significant.

These results do not support the widely held view that the concentration of immunoglobulins in the serum are profoundly reduced, some to the point of virtual disappearance, after lethal doses of radiation. There appears to be a particularly marked effect on IgA, but even this protein by no means disappears. The difference between the present and previous conclusions is probably attributable in large measure to the greater sensitivity of the

technique of single radial diffusion, which, with the antisera used, yielded quantitative estimates of antigen down to lower concentrations than were required for this study (about 0.10 mg/ml. for IgM; 0.01 mg/ml. for IgG2a; 0.05 unit for IgA; 0.05 unit for IgG1). Other factors which may have influenced the results are the age, strain and immunological status of the mice. These were older than those commonly used for such experiments and had relatively high initial concentrations, at least of IgM and IgG2a. According to Sassen *et al.*<sup>4</sup>, some kinds of infection can influence the concentration of Ig under similar experimental conditions, and it would be difficult to exclude the operation of such a factor.

Fig. 1. Changes in the concentration of immunoglobulins after lethal total-body X-irradiation (mean  $\pm$  S.E.). a, IgA; b, IgG1; c, IgG2a; d, IgM. Values for IgA and IgG1 are expressed as units, the concentration in a large pool of normal serum being taken as 1 unit. Values for IgG2a and IgM are in mg/ml. ●, Non-irradiated mice; ○, irradiated mice.

The reduction in the concentration of Ig after irradiation probably results largely from interference with synthesis after damage to lymphoid tissue and particularly from proliferating cells of the plasmacytic series. The possible intervention of other factors, such as loss of protein through the intestinal wall<sup>10</sup>, and changes in the water-content of the body, however, make it impossible, on the basis of our results, to say exactly when and to what extent the synthesis of Ig is disrupted.

This work was begun while the authors were colleagues at the MRC Radiobiological Research Unit, Harwell. One of us (H. B.) was aided by a grant from Euratom.

## Hepatic Suppression of Sensitization to Antigen absorbed into the Portal System

THE position of the liver between the gastrointestinal tract and the general circulation provides certain metabolic advantages. If, in addition, the liver functions to prevent sensitization to potential antigens contained in food and absorbed into the portal system, then this interposition is also immunologically important.

Specific immunological unresponsiveness to picryl chloride has been induced in adult guinea-pigs by feeding this hapten to the animal before application to the skin<sup>1</sup>. Picryl chloride administered to mesenteric veins of guinea-pigs produced effects similar to oral feeding<sup>2</sup>; this phenomenon is referred to as the Chase-Sulzberger effect and remains unexplained. The underlying mechanism, however, seems to depend on the fact that antigen is carried to the liver before it reaches either the lymphatic system or the general circulation. In this communication we describe experiments which indicate that repeated oral feeding of 1-chloro 2,4-dinitrobenzene (DNCB) to adult dogs before subcutaneous injection suppresses the formation of specific circulating antibodies and that diversion of portal flow from the liver abolishes this effect.

Experiments were carried out on twenty healthy adult (10–15 kg) mongrel dogs. The animals were divided into four equal groups, and the following procedures were carried out. In group 1 concentrations of anti-dinitrophenol (DNP) antibody were measured in samples of blood collected from five dogs which had no known exposure to DNCB. In group 2 a solution of 8 mg of 1-chloro 2,4-dinitrobenzene (DNCB) in 1 ml. of olive oil was injected subcutaneously into each of five dogs in quantities of 400γ on day 1, and 200γ on days 5, 8, 11, and 15. On the twenty-sixth day after the first injection samples of blood were collected and levels of anti-DNP antibody were determined.

In group 3 DNCB dissolved in corn oil (20 mg/ml.) was mixed with ground beef and fed to five dogs. A pellet of beef containing 10 mg of the hapten was placed on the back of the dog's tongue with a spatula and swallowing was induced, according to the following schedule: days 1–6, 10 mg of DNCB/day; days 7–14, no DNCB; days 15–20, 10 mg DNCB/day; days 21–33, no DNCB. On the thirty-fourth day DNCB was injected subcutaneously according to the same schedule followed in dogs in group 2. Twenty-six days after the first subcutaneous injection samples of blood were collected for determinations of antibody.

In group 4 under intravenous 'Nembutal' anaesthesia complete portacaval transposition was carried out in five dogs through a midline abdominal incision. After dividing the portal vein and inferior vena cava just inferior to the hilum of the liver, the proximal cut end of each vein was connected to the distal cut end of the other by two short segments of thick walled silastic tubing measuring 8 mm in internal diameter. With the exception of one animal that died during the first 24 h after operation the post-operative courses were uneventful. On the seventieth post-operative day oral feedings of DNCB were started and thereafter the regimen was identical to that carried out in animals in group 3.

Samples of blood were centrifuged immediately at 15g for 10 min at 37° C. The serum was incubated at 56° C for 30 min to inactivate complement and was then absorbed with washed human erythrocytes to remove non-specific agglutinins. The titre of anti-DNP antibodies was then determined by the haemagglutination technique of Bullock and Kantor<sup>3</sup>. For this purpose serum was diluted with saline buffer and tested in concentrations which ranged from 1 to 2–1 to 1,024.

Titres of antibody in the nineteen dogs tested are shown in Fig. 1. Serum from the five animals with no known contact with DNCB (group 1) contained no measurable antibody. Titres of antibody in animals that received only subcutaneous injections of DNCB (group 2) ranged from 1 to 64–1 to 512. In contrast were the dogs repeatedly fed antigen before subcutaneous injections (group 3). The sera of two contained no measurable amounts of antibody, in two the titres were 1 to 4 and in one the titre was 1 to 16.

Fig. 1. Titres of serum antibodies to DNP in each dog. Group 1, no known exposure to DNCB. Group 2, DNCB injected subcutaneously. Group 3, DNCB feedings followed by subcutaneous injection. Group 4, portacaval transposition followed by oral feedings and subcutaneous injection.

Sera of dogs undergoing portacaval transposition (group 4) contained antibody in practically identical amounts to sera of dogs in group 2, ranging from 1 to 64-1 to 256. Three to four weeks after operating, femoral venograms showed that contrast material entered the hepatic end of the portal vein from the inferior vena cava. After an interval of 4-5 months large collateral veins appeared on the abdominal wall. Injection of X-ray contrast material into mesenteric veins at this time showed that flow had ceased from the portal vein into the inferior vena cava. No blood from the portal vein entered the liver because all collaterals from the obstructed portal vein bypassed the liver and flowed into the caval or azygos systems.

These experiments indicate that when DNCB is fed to dogs the expected increase in serum antibody after subcutaneous injection of this antigen does not occur. With respect to circulating haemagglutinating antibody therefore the Chase-Sulzberger effect applies in dogs as in guinea-pigs. The effectiveness of preliminary oral feedings was abolished when portal blood was diverted from the liver and this supports the view that circulation of antigen to the liver before entry into lymphatics or into the general circulation impairs ability to recognize or react with the antigen on subsequent contact. Earlier experiments in rats indicate that when complex products of cell disruption were injected into the portal vein, skin grafts from donors of disrupted cells survived four or five times longer than similar grafts in control animals in which disrupted cells were injected into a systemic vein<sup>4</sup>.

Studies of the hepatic reticuloendothelial system have suggested a mechanism of immunological unresponsiveness after circulation of antigen in portal blood to the liver<sup>5</sup>. Immunological conjugates formed on absorption of hapten into portal blood course through liver sinusoids where the complexes are phagocytosed by Kupffer cells. As a result, the particulate or "phagocytosable" portion of the complex which is usually taken up by immuno-competent macrophages to induce the immunological response is separated instead and perhaps permanently deposited in Kupffer cells<sup>6</sup>. Evidence indicates that Kupffer cells specifically and the liver generally are incapable of producing antibodies<sup>7,8</sup>. The soluble portion of the antigen, on the other hand, which is unable to induce antibody production by itself, enters small lymphocytes, rendering them immunologically incompetent, and unresponsiveness results.

Considered in these terms the strategic interposition of liver between the gastrointestinal tract and the general circulation insures against sensitization to simple antigens in food which are absorbed into the portal system. On the other hand, bacteria, lipids containing ten or more carbon atoms and protein are absorbed into lacteals and are transported through mesenteric lymph nodes to the blood<sup>9-11</sup>. It may be significant in this respect that the mesenteric lymph node system reaches its highest development in mammals, a species distinguished by reliance of the newborn on lipid absorbed from the gastrointestinal tract.

Increased concentrations of gamma-globulin characterize patients with advanced cirrhosis and the increase in gamma-globulin consists almost entirely of immunologically active protein<sup>12</sup>. It is tempting to speculate that derangements in the wall of the sinusoid, described by Schaffner and Popper, or spontaneous portacaval shunts, or both, may so alter the disposition of antigen that the effectiveness of the liver in suppressing sensitization to absorbed antigen is lost<sup>13</sup>.

Dogs developed high titres of serum antibody after subcutaneous injection of the simple chemical DNCB. When this antigen was repeatedly fed to dogs for 4 weeks and the animals were then challenged by subcutaneous injections, there was no antibody response. The effectiveness of oral feeding was abolished in dogs undergoing portacaval transposition.

This work was supported by grants from the National Institutes of Health, US Public Health Service.

## HAEMATOLOGY

### Non-identity of the $\alpha$ -Granules of Human Blood Platelets with Typical Lysosomes

PLATELETS are known to be important in blood coagulation, in haemostasis and in thrombosis, and during this process they undergo a series of profound morphological and biochemical changes termed viscous metamorphosis. Platelets contain a wide variety of subcellular organelles<sup>1-5</sup>, and some of them are altered during viscous metamorphosis<sup>6,7</sup>. The most prominent organelles are the very osmiophilic  $\alpha$ -granules, which disappear shortly after the onset of viscous metamorphosis<sup>8</sup>. The  $\alpha$ -granules are believed by some to be the chief source of platelet factor 3, the pro-coagulant phospholipoprotein of platelets<sup>4,8,9</sup>; others regard them as storage organelles for serotonin<sup>10,11</sup> and adenosine triphosphate (ATP)<sup>12</sup>. On the other hand, several authors<sup>13-15</sup> have believed that platelets contain granules with lysosomal activity, and recently Marcus *et al.*<sup>16</sup> claimed to have identified as lysosomes  $\alpha$ -granules isolated from platelet homogenates. Evidence from electron microscopy has encouraged<sup>17</sup> a comparison of the  $\alpha$ -granules with the enzyme-secreting vesicles of the pancreas, and similar particles have been described with the same typical striated internal structure in endothelial cells<sup>18</sup>. Thus there are discrepancies in the interpretation of the nature and function of the  $\alpha$ -granules and a re-investigation of the problem seemed justified.

Human blood platelets were isolated from 15-25 l. of acid citrate dextrose-blood and washed twice, as described before<sup>9</sup>, within 24 h of the collection of the blood.

A suspension containing about  $3 \times 10^6$  platelets/mm<sup>3</sup> was prepared in isotonic imidazole buffer, pH 7.2, containing 2.7 mmolar ethylenediamine tetraacetic acid (EDTA), and homogenized in the cold using an MSE mechanical blender at 10,000 r.p.m. for 6 min. To remove cell fragments and aggregated material the homogenate was centrifuged first for 10 min at 1,200g, then for 20 min at 6,800g, in the swing-out head of a refrigerated centrifuge; the sediments were discarded. The organelles were then sedimented (30 min, 12,000g), and resuspended in the original imidazole buffer. An aliquot of 1.2 ml. of this suspension was layered onto a sucrose density gradient prepared 10 h earlier in a 5 ml. centrifuge tube. For a typical gradient the following concentrations and amounts of sucrose solution were used (from bottom upwards):

0.25 ml. of 45 per cent (g of sucrose/100 g solution), 0.5 ml. of 40 per cent, 0.75 ml. of 37.5 per cent, 0.5 ml. of 35 per cent, 1.0 ml. of 27.5 per cent, and 0.5 ml. of 25 per cent. Separation of the organelles was accomplished by centrifugation at 100,000*g* for 90 min at 2° C (Spinco, model L, with an 'SW-39L' rotor). The zones obtained were displaced from the centrifuge tube by sucrose solution of high density, which was run into the bottom of the tube through a fine capillary. Fractions corresponding to the visible zones were collected. Densities were determined by refractometry, with the aid of a sucrose calibration curve. Characterization of the isolated zones was carried out either on washed material (sedimented from a larger volume of added imidazole buffer at 15,500*g* for 30 min, and resuspended in the same buffer) or directly on the fractions collected from several separations carried out simultaneously. Protein was determined by the biuret method, and phosphate by the procedure described by Bartlett<sup>20</sup>. Acid phosphatase was estimated with *p*-nitrophenylphosphate as substrate, using the Boehringer method; for  $\beta$ -glucuronidase the method in bulletin 105 by the Sigma Chemical Company was used, and the test was carried out in 0.1 molar acetate buffer, pH 4.5. Cathepsin was determined by the method of Gianetto and de Duve<sup>21</sup>. To estimate the activity of platelet factor 3 the method of Egli<sup>22</sup>, and/or the "Stypven"-time<sup>23</sup>, were used. In order to liberate enzyme activities, "Triton-X-100" was added to the organelle fractions.

By the method described, five well defined zones were obtained after density gradient centrifugation. (With a slightly modified procedure a sixth zone, located above the others and consisting of membrane material, is found; this is absent when the procedure described here is followed.)

The characteristics of the five different zones, in the order of increasing densities, are as follows: zone *a* consists mainly of soluble components, and zone *b* is composed mainly of the  $\alpha$ -granules (see Fig. 1). This fraction is rich in acid phosphatase, but has negligible cathepsin and  $\beta$ -glucuronidase activities; it has the greatest content of phosphorus of all the five zones, and the most (absolute and specific) platelet factor 3 activity, which is further increased on disruption of the granules.

Zone *c* follows zone *b* closely. It consists of microvesicles of variable diameter (Fig. 2), most of them surrounded by a single membrane, interspersed with still smaller and darker bodies. This fraction is characterized by cathepsin and  $\beta$ -glucuronidase activities. Acid phosphatase is also present, although the activity is less than that observed in zone *b*. As already reported<sup>24</sup>, immunoelectrophoresis of the disrupted material reveals several plasma proteins, indicating the presence of micropinocytosis vacuoles. No soluble plasma proteins were detected by this method in the  $\alpha$ -granule fraction.

Fig. 1. Electron micrograph of fraction *b* containing  $\alpha$ -granules (glutaraldehyde-osmium tetroxide fixation). ( $\times 33,840$ .)

Fig. 2. Electron micrograph of fraction *c* containing microvesicles (glutaraldehyde-osmium tetroxide fixation). ( $\times 33,840$ .)

Zone *d* consists mainly of mitochondria, with some ill-defined membrane material and glycogen grains. Zone *e*, from the bottom of the centrifuge tube, contains all the material with densities equal to or higher than the most concentrated part of the gradient.

A more detailed description of this and the other fractions will be published elsewhere.

These results confirm the idea that blood platelets contain lysosomes; they do not agree, however, with the concept that the  $\alpha$ -granules are typical lysosomes, if such are defined as sedimentable structures containing several acid hydrolases<sup>25</sup>. Table 1 shows the activities of three typical lysosomal enzymes, that is, acid phosphatase, cathepsin and  $\beta$ -glucuronidase, in zones *b* and *c* of the density gradient. It is evident from these values that the structures contained in fraction *c* fulfil much better than the  $\alpha$ -granules the requirements of the definition of lysosomes just given; however, it should be noted that several types of lysosomes have been described, which differ in their morphology as well as in their content of enzymes<sup>26</sup>.

Table 1. ACTIVITIES OF ACID HYDROLASES IN ZONE *b* ( $\alpha$ -GRANULES) AND ZONE *c* (MICROVESICLES)

Zone (localization, expressed as density of sucrose in gradient)	Acid phosphatase (Bessey units/10 $\mu$ g N)	$\beta$ -Glucuronidase ( $\mu$ g phenolphthalein/10 $\mu$ g N/h)	Cathepsin ( $\mu$ g tyrosine/10 $\mu$ g N/h)
<i>b</i> (1.108-1.118)	156	15	17
<i>c</i> (1.156-1.163)	78.2	118	434

The organelles were disrupted with "Triton-X-100". Without this pretreatment no catheptic and only insignificant amounts of  $\beta$ -glucuronidase activities were discernible, while acid phosphatase was less in both zones. The reported values are taken from one of fifty-four separation experiments.

Does the high acid phosphatase content of the  $\alpha$ -granules justify their classification as lysosomes? It must be pointed out that the presence of an acid hydrolase alone is not enough to identify an organelle as a lysosome (compare the high  $\beta$ -glucuronidase activities of microsome<sup>27,28</sup>). It would be important to know more about the specificity and the functional significance of the granular phosphatase. Very little is known, however, about the function of the  $\alpha$ -granules themselves. Although they have a high phospholipoprotein content, it remains uncertain whether they, or their breakdown products, remain confined to the intracellular space during viscous metamorphosis or whether they are released to take part in plasmatic blood coagulation.

In summary, it has been demonstrated that the  $\alpha$ -granules of human blood platelets can be separated from a typical, though morphologically heterogeneous, lysosomal fraction characterized by its comparatively high content of acid phosphatase, cathepsin and  $\beta$ -glucuronidase. Of these acid hydrolases, only acid phosphatase is present in large amounts in the  $\alpha$ -granule fraction. The question of whether this observation, along with the

characteristic morphology of these organelles (compare also ref. 18), permits the classification of the  $\alpha$ -granules among the lysosomes needs further clarification.

We thank Professor E. Weibel for his kind co-operation and Miss S. Weber for technical assistance.

## Immune Lysis of AET-treated Normal Red Cells (PNH-like Cells)

NORMAL human red cells treated with the sulphydryl compounds AET (2-aminoethylisothiuronium bromide) or cysteine in suitable conditions develop some of the characters of the red cells of paroxysmal nocturnal haemoglobinuria (PNH)<sup>1</sup>. In particular, they lyse in slightly acidified fresh compatible normal serum (pH 6.5). Mengel *et al.*<sup>2</sup> later reported that they had obtained similar results by incubating normal red cells with another sulphydryl compound, reduced glutathione. Lysis in acidified serum (a positive Ham test) has been considered characteristic of PNH, and appears to be an expression of the peculiar sensitivity of such cells to lysis by complement. This has been investigated with a complement lysis sensitivity test based on the use of red cells sensitized with a constant, optimal amount of an anti-I antibody and then treated with graded amounts of fresh compatible normal human serum as a source of complement. PNH cells were found to consist of two populations, one markedly sensitive to lysis by C' (about twenty-five times more sensitive than normal cells) and the other usually only slightly more (about twice) sensitive than normal cells. The very sensitive population of cells and the existence of two populations of cells are distinguishing characteristics of PNH which have not so far been found in health or in any other disease state.

Because of the apparent similarities between PNH cells and normal cells treated with AET (AET cells), it seemed worth while to investigate the sensitivity of the latter to immune lysis and to elucidate the relative roles of C' and antibody in bringing about their lysis. The techniques

used were slightly modified versions of those already described<sup>3,4</sup>. The same anti-I antibody of high haemolytic potency, however, was used.

Normal red cells, AET cells and the red cells from two PNH patients, both suffering from a comparatively mild form of the disease, were tested. The AET cells were prepared<sup>1</sup> using an 8 per cent (w/v) (0.285 molar) solution of the chemical.

The complement lysis sensitivity titre (C'L.S. H<sub>50</sub> units) of AET cells (exposed to 8 per cent (w/v) AET for 9 min) was approximately twenty times more than normal (range 15–25), that is, AET cells were found to require only about one-twentieth the amount of C' for 50 per cent lysis compared with normal cells sensitized with the same amount of antibody. Thus in this respect AET cells resemble the more sensitive population of PNH cells. In contrast to PNH blood, however, the haemolysis of anti-I-sensitized AET cells by increasing amounts of C' occurs as a simple function of the concentration of C'; that is, when the logarithm of  $y/(1-y)$  is plotted against the logarithm of concentration of complement (where  $y$  is the fraction of cells lysed), a straight line is obtained and there is no evidence of two populations of cells as is characteristic of PNH (Fig. 1). The degree to which AET cells are sensitive to C' lysis was found to be related to the concentration of AET and to the time to which the normal cells were exposed to its action (Fig. 2). As with normal cells<sup>3</sup>, the line may curve at high C' concentrations.

The amount of lysis which took place after incubation of AET cells in acidified compatible normal serum was related to their complement sensitivity (Table 1). Analysis of the sensitivity to complement lysis of AET cells before and after exposure to acidified serum showed that the cells surviving this treatment were less sensitive to complement lysis than the original cell population.

It is worth noting that AET cells which survived the Ham test were agglutinated by a potent anti-whole-serum antiglobulin serum, while they were not agglutinated by the antiglobulin reagent before exposure to acidified compatible normal serum. Similar observations have been made with PNH cells<sup>5</sup>.

The relative ability of AET and PNH cells to adsorb antibody compared with that of normal cells was calculated by determining the ratio of the percentage of antibody adsorbed by a given number of each type of cell. The ratio for AET cells was 2.7 and that for PNH

Fig. 1. Representative complement lysis sensitivity curves of normal, PNH and AET-treated cells.

Fig. 2. Complement lysis sensitivity curves of normal cells and of normal cells exposed for different periods of time to 8 per cent (w/v) AET.

cells was 2.0 (ratio for normal cells 1.0). This indicates that the behaviour of the two types of cells is not very different in this respect. The ratio for papainized normal cells has been found to be as high as 7.9 (ref. 4).

The amount of complement and the amount of antibody were measured in a test system before and after reaction with normal cells and with AET cells, respectively, and the ratio of complement fixed/antibody adsorbed was calculated. The amount of complement fixed for each unit of antibody adsorbed seemed to be the same for both types of cells.

Table 1. RELATION OF COMPLEMENT LYSIS SENSITIVITY OF NORMAL CELLS EXPOSED TO 8 PER CENT (W/V) AET TO LYSIS IN THE HAM TEST

Time of exposure (min)	Ham test percentage of lysis (a)	C.L.S. $H_{50}$ units (b)	Ratio (a)/(b)
3	5	3.33	1.50
6	24	8.70	2.75
9	36	16.66	2.16

These experiments indicate that AET cells are very sensitive to the lytic action of complement. They adsorb about 2.7 times as much antibody as normal cells, but this difference in adsorption of antibody does not explain the approximately twenty-fold increase in complement sensitivity of AET cells compared with normal cells. In this respect therefore AET cells behave in a manner similar to the sensitive population of PNH cells. It is tempting to believe that in both cases there is an abnormality of the red cell membrane which renders the cells more sensitive than normal to the action of the late-acting components of the complement sequence.

Mengel *et al.*<sup>2</sup> reported that both PNH cells and normal cells treated with reduced glutathione are more sensitive than normal to lysis in hydrogen peroxide and that in both cases lipids extracted from the cells form increased and comparable quantities of lipid peroxides during exposure to ultra-violet light. The authors concluded that the effect of reduced glutathione in producing PNH-like cells is oxidative, ultimately involving the red cell lipids, and they suggested that in PNH the corpuscular defect which renders the cells susceptible to lysis is related to peroxidation of red cell lipids. Our data indicate that chemical damage can increase a cell's sensitivity to lysis by complement.

Irrespective of the mechanism by which sulphhydryl compounds alter the normal red cell membrane, either by a modification of their lipids or proteins (or both), it seems reasonable to conclude that normal red cells treated

with sulphhydryl compounds such as AET develop damage to their surfaces which may be similar to that occurring spontaneously in PNH. Further study of AET cells should throw light on the nature of the PNH cell defect; it could also provide clues to the way in which the late-acting components of complement bring about haemolysis.

## BIOCHEMISTRY

### Enhancing Effect of Insulin on the Tuberculin Reaction in the Albino Rat

SEVERAL authors have suggested that insulin is involved in inflammatory and hypersensitivity reactions<sup>1,2</sup>. It is known<sup>2,3</sup> that tuberculin-type skin sensitivity reactions to purified protein derivative (PPD) in the guinea-pig can be depressed by alloxan, and this depression can be partially reversed by the administration of insulin<sup>2</sup>. In the rat<sup>1</sup> insulin intensifies inflammatory and immunological reactivity. It was thus of interest to determine whether tuberculin reactions in the rat (a relatively poor reactor to delayed-type hypersensitivity) could be intensified when insulin was given at the same time.

Purified protein derivative (Parke Davis and Co. second strength tablets, 0.05 ml./tablet) was used at a concentration of 0.1 mg/ml. The buffer used in the injections was supplied with the tablets. 'Gelatin' (Difco) was used at a concentration of 180 mg/ml. of buffer. Regular insulin ('Iletin', Lilly) was injected 1 h before and again 3 and 6 h after challenge (or, alternatively, incorporated into the 'Gelatin' mixture at a concentration of 2 U/ml.). PPD, by itself or in combination, was administered under light ether anaesthesia to the dorsal skin, the lip or the foot pad of the rear paw in a volume of 0.1 ml. A control injection of buffer or other carrier without PPD was given to a similar site, usually on the opposite side of the animal. Rats (Wistar derived, Greenacres Controlled Flora) were challenged throughout these experiments at a weight of 140–160 g.

Delayed-type hypersensitivity was induced by injecting 70–80 g rats subcutaneously in each of two sites with 0.25 ml. of Freund's complete adjuvant containing killed, dried *M. tuberculosis* (Lederle) to give a total of 1 mg of the injected rat. PPD challenge was carried out 35 days after sensitization.

Table 1 shows that paw challenge in rats treated with 2 U of insulin gave a high percentage of positive reactions, while untreated rats were always negative. The use of

Table 1. PPD REACTIONS IN THE RAT

Challenge site	Treatment	Result No. reacting/No. used
Paw	1 U of insulin	1/6
Paw	2 U of insulin	20/29, 9/29
Lip		0/29
Skin		0/29
Skin	None	0/8
Lip		0/8
Paw		0/8

the lip and skin as a site of challenge in either treated or untreated animals also gave negative results.

A mixture of 'Gelatin', buffer and insulin, containing the usual 0.01 mg of PPD, intensified the gross reaction to PPD in rats sensitive with *M. tuberculosis*. After 24 h the skin showed lesions with an overall average size of 15–18 mm, as compared with control sites containing only 'Gelatin' and insulin which averaged 6–10 mm.

Although the combination of insulin and 'Gelatin' with PPD intensified the gross skin reaction, it was impossible to grade such lesions microscopically. Within a few hours the 'Gelatin' caused polymorphs to aggregate at the site of injection; this was increased in the presence of insulin.

The induction of a tuberculin reaction in the sensitized rat treated with insulin, in contrast to the lack of reaction in the untreated sensitized rat, emphasizes the importance of insulin or concentrations of glucose in hypersensitivity reactions. Such results are consistent with observations of systemic anaphylaxis in the mouse and rat<sup>1,2</sup> and tuberculin reactions in the guinea-pig<sup>2,3</sup>. The relative importance of insulin (glycaemic levels or the related energy pathways involved) has still to be established. The present experiments, however, extend the use of rats in delayed-type hypersensitivity experiments.

### Inhibition of DNA-dependent RNA Polymerase by 4-Nitroquinoline-N-oxide in Isolated Nuclei

4-NITROQUINOLINE-N-OXIDE (4-NQO) is a potent carcinogen<sup>1</sup> and mutagen<sup>2</sup>, which has been shown to induce tumours in mammals<sup>3</sup>, cause nuclear abnormalities in *Tetrahymena*<sup>4</sup> and induce alterations in tissue culture cell nuclei<sup>5</sup>.

The activity of DNA-dependent RNA polymerase (E.C.2.7.7.6) was assayed on intact isolated nuclei from Chang liver cells grown in spinner cultures<sup>6</sup>, using a modified Eagle's suspension medium with foetal calf serum. 4-NQO was added in a concentration of 10<sup>-3</sup> molar in Hanks balanced salt solution. Experimental cultures were exposed to 4-NQO for 1 h followed by media for 1 h. The cells were collected by centrifugation at 1,000g for 10 min at 4° C and the resultant pellet was resuspended twice in 10 ml. of Eagle's medium and centrifuged at 1,000g for 10 min after each suspension. After the final centrifugation the cells were suspended in 2.0 ml. of 0.5 molar sucrose containing 2.5 mmolar magnesium chloride and homogenized in a Potter-Elvehjem homogenizer intermittently at 1,000 r.p.m. for 5 min at 4° C. The homogenate was centrifuged at 5,000g at 4° C for 15 min and the crude nuclear fraction was collected and suspended in 0.5 molar sucrose in the presence of 2.5 mmolar magnesium chloride and centrifuged at 80,000g for 5 min at 4° C.

The purified nuclear fraction was suspended in an assay mixture containing 100 mmolar *tris* buffer, 3.0 mmolar mercaptoethanol, 20 mmolar sodium fluoride, 3 mmolar manganese chloride, 60 mmolar potassium chloride and 160  $\mu$ molar ammonium sulphate. To the assay medium, 0.5 mmolar of each of the RNA precursors (ATP, GTP, UTP and CTP) were added to the assay mixture at a final volume of 0.5 ml. at pH 7.4. Similar assay mixtures have been used in previous studies of nuclear RNA polymerase activity<sup>7,8</sup>. The carbon-14 label (0.5  $\mu$ c.) was introduced in labelled ATP (specific activity, 30.7 mc./

mmole) or labelled CTP (specific activity, 20.6 mc./mmole). After incubation for 20 min at 37° C, 1 ml. of a saturated sodium pyrophosphate solution and 1 mg of crude yeast RNA were added and the reaction was terminated by the addition of 4 ml. of cold 0.5 molar perchloric acid. The precipitate was collected on a 'Millipore' filter (pore diameter, 0.2  $\mu$ ) and washed with two 10 ml. volumes of cold perchloric acid, two 10 ml. portions of cold ethanol and two 10 ml. portions of ethanol:ether (1:1, v/v). The filter and precipitate were dissolved in 0.4 ml. of 'Hyamine' and counted in a liquid scintillation counter.

The incorporation of carbon-14 into acid insoluble RNA in the controls required the presence of all four precursors as has previously been shown<sup>9</sup>. Table 1 summarizes the data in terms of  $\mu$ moles of labelled ribonucleotide triphosphate incorporated into the acid insoluble fraction/mg of DNA estimated by Burton's method<sup>10</sup>. Incorporation of carbon-14 into the acid insoluble fraction (RNA) was inhibited by low temperatures, RNase, DNase and actinomycin D as has been shown by other investigators<sup>7</sup>. Inhibition was also caused by the deletion of one or more of the ribonucleotide precursors.

Table 1

Assay condition (at 37° except as noted)	$\mu$ Moles of acid insoluble <sup>14</sup> C/mg of DNA	
	Control nuclei	Pretreated (10 <sup>-3</sup> molar 4-NQO)
Complete (0.0 min)	0.07	0.04
Complete (20 min)	3.85	1.90
Complete (40 min)	6.09	2.32
Complete (60 min)	8.56	4.40
Complete (120 min)	10.06	5.40
Complete (120 min, 0° C)	0.14	0.07
No <sup>14</sup> C-ATP ( <sup>14</sup> C-CTP substituted) (20 min)	0.43	1.05
No CTP (20 min)	0.61	0.95
No UTP (20 min)	0.38	0.78
No (NH <sub>4</sub> ) <sub>2</sub> SO <sub>4</sub> (20 min)	5.63	1.45
Complete + 50 mg/ml. of DNase (20 min)	0.43	0.33
Complete + 200 mg/ml. of RNase (20 min)	0.57	0.39
Complete + 25 mg of actinomycin D (20 min)	0.23	0.17

An unexpected finding was the lowered dependence of groups treated with 4-NQO on the presence of all four precursors. Control groups in assay mixture, with ATP, UTP or CTP omitted, showed smaller contents of RNA polymerase than groups pretreated with 4-NQO when assayed with one nucleotide omitted.

Sucrose density gradient centrifugation of the cytoplasmic RNA produced after exposure to 4-NQO has shown that this RNA species exhibits a sedimentation constant of less than 8S with most of it less than 4S. RNA sedimenting in this region was greater by a factor of 3 to 5 than the controls. Cultures treated with 4-NQO showed an almost complete absence of RNA components of higher S-coefficients. Base sequence studies on this fraction are now in progress. This fraction was lacking in amino-acid accepting ability.

The lower dependence of RNA polymerase activity in 4-NQO treated nuclei may be caused by increased utilization of nuclear RNA as a ribosetriphosphate pool or to the partial substitution of another ribonucleotide in the assay medium for the one that is absent from the assay medium. We believe the second alternative to be the correct one, because it is conceivable that 4-NQO when complexed with the DNA molecule<sup>11</sup> may cause misreading of the template with a concomitant increase in RNA polymerase activity above as a result of base substitution.

The ability of 4-NQO to inhibit RNA polymerase was not as marked as that seen with actinomycin D. This may be due to the relatively small size of the 4-NQO molecule as compared with actinomycin D<sup>12</sup> and is thus less effective in blocking RNA transcription, but may cause misreading of the template during RNA synthesis. A recent morphological observation<sup>4</sup> suggests that 4-NQO may also induce errors in DNA replication as it was only effective by the criteria used if present during DNA replication.

## Proteins, Persulphate and Disc Electrophoresis

POLYACRYLAMIDE electrophoresis of purified chick interferon at pH 8.9 by methods similar to that of Davis<sup>1</sup> gave an average recovery of activity of about 30 per cent<sup>2,3</sup>. The recovery could be improved by omitting the spacer and sample gels. Electrophoresis at pH 4.3 by a method similar to that of Reisfeld *et al.*<sup>4</sup> invariably abolished all or nearly all interferon activity<sup>5</sup>.

One of the materials used by both Davis and Reisfeld for polymerizing the small-pore gels is ammonium persulphate, and we suspected that this substance, at least under acid conditions, destroyed interferon. We therefore incubated (18 h at 4° C) crude chick interferon at pH 4.3 and pH 8.9 (in 0.3 molar acetate and 0.3 molar *tris* buffer, respectively) with and without persulphate (0.0064 molar, the concentration used by Reisfeld for polymerization). Activity completely disappeared in the acidic sample containing persulphate but not at all in the other three preparations (Table 1). Highly purified interferon was stable to incubation at pH 4.3 but only in the absence of persulphate. Similar incubation with ammonium chloride caused no loss of activity, proving that destruction was not due to the cation. When riboflavin (0.0005 per cent) was used instead of persulphate to catalyse the polymerization of the gels, good recoveries of interferon were also obtained after electrophoresis at pH 4.3.

Persulphate is widely used in polyacrylamide gel electrophoresis and therefore it seemed worth while to investigate its effect on three other biologically active materials containing protein, poliomyelitis virus, ribonuclease and insulin.

Live, concentrated<sup>6</sup> poliomyelitis virus (type 1, Brunenders), containing 880 "D-units"/ml. (ref. 7), crystalline pancreatic ribonuclease (100 µg/ml.), and crystalline insulin (50 µg/ml., 23.16 U/mg) were incubated in the same way as chick interferon. The "D" antigen content

of the re-neutralized poliomyelitis virus samples was assessed by the method of Beale and Mason<sup>8</sup>, and the potency of the ribonuclease solutions by that of Anfinsen *et al.*<sup>9</sup> (Table 1). Poliomyelitis virus "D" antigen was completely destroyed by persulphate at pH 4.3, and perhaps to some extent also at pH 8.9, but no significant loss occurred at either pH in the absence of persulphate. Ribonuclease, on the other hand, was destroyed extensively in the presence of alkaline persulphate, though some destruction may also have been caused by acid persulphate.

The effect of persulphate on insulin was investigated by subjecting it to polyacrylamide gel electrophoresis under various conditions and then staining the gels with amido black. Alkaline and acid electrophoresis was carried out by methods similar to those of Davis<sup>1</sup> and Reisfeld *et al.*<sup>4</sup>, except for the omission of sample and spacer gels. Insulin samples intended for electrophoresis at pH 4.3 or pH 8.9 were first adjusted to pH 7.4 or pH 6.0, respectively, and applied to the gels in 0.02 molar phosphate buffers at these values. At pH 4.3 the band in the persulphate-catalysed gel was definitely less intense than the corresponding one in the riboflavin-catalysed gel (Fig. 1a and b). When the samples were pre-incubated at pH 4.3 without persulphate and then subjected to electrophoresis at pH 4.3 in both types of gel, no band at all could be detected in the persulphate gel, but the pretreatment did not seem to have diminished the band intensity in the riboflavin gel (Fig. 1c and d). Pretreatment at pH 4.3 in the presence of persulphate again revealed the absence of any band in the persulphate gel but it also reduced the intensity of the band in the riboflavin gel. Electrophoresis at pH 8.9 produced stained bands of approximately equal intensity in both gels, but the band in the persulphate-catalysed gel had a lower *R<sub>Br-phenol blue</sub>* value than the sample in the riboflavin gel (Fig. 1g and h). Pre-incubation pH 8.9 without persulphate did not influence these results, but pre-incubation in the presence of persulphate completely prevented formation of any band in either type of gel (Fig. 1k). Results of the work with insulin are summarized in Table 2. (It should be noted that the fact that the biological activity of insulin is not stable at pH 8.9 (ref. 10) has no bearing on the main theme of this communication.)

Fig. 1. Polyacrylamide electrophoresis of insulin. Direction of travel was from the top downwards. The sharp band at the bottom of gels g, h and k is bromophenol blue. Electrophoresis in gels a, b, c and d was carried out at pH 4.3, in gels h, g and k at pH 8.9. The current per gel was kept at about 0.6 m.amp. For details see text and Table 2.

Table 1. EFFECT OF AMMONIUM PERSULPHATE AT pH 4.3 AND pH 8.9 ON ACTIVITIES OF CHICK INTERFERON, POLIOMYELITIS VIRUS AND RIBONUCLEASE

(k) pH 8.9 + 0.0064 molar persulphate	Persulphate	8.9 -
(l) pH 8.9 + 0.0064 molar persulphate	Riboflavine	8.9 -

\* Retardation of band, presumably indicating a change in the protein.

These findings show that a number of quite diverse proteins are affected by even a low concentration of either acid or alkaline ammonium persulphate, present either in the solvent or in the polyacrylamide gel. Attempts to remove persulphate from a gel column by pre-electrophoresis at pH 4.3 (6 m.amp./tube, 2 h) were not successful because insulin (after incubation at pH 4.3 without persulphate) still gave no band after electrophoresis in a persulphate gel, but, as already mentioned, one was produced in a riboflavine gel.

Although the mode of action of persulphate is unknown, its use as a catalyst for the polymerization of acrylamide gels does lead to changes of some proteins and can thus give rise to artefacts. It may therefore be advisable to re-examine some of the results reported from electrophoresis in persulphate catalysed gels and to polymerize gels with riboflavine instead of persulphate.

*Note added in proof.* Since the submission of this communication for publication, J. M. Brewer (*Science*, 156, 256; 1967) has shown that enolase is degraded by persulphate, but only in the presence of 8 molar urea.

## Urinary Crystals and their Relation to Stone Formation

A VARIETY of crystalline substances, particularly urates, oxalates and phosphates<sup>1,2</sup>, have been described in urine, but the relation of these crystals to the pathogenesis of calculi of the urinary tract, which commonly contain some or all of these materials, has never been established. Nor is it known which of these crystals (if any) form in the urinary tract and which develop in the urine outside the body. We have therefore studied the crystalline material in freshly voided urine from normal and stone-forming subjects to determine whether any material is present which might be regarded as the nucleus of a calculus.

The initial study involved ten male hypercalciuric stone-formers and ten male normal controls on unrestricted fluid intake and a variety of diets. Urine was collected at hourly intervals during the day in double-walled, silvered Dewar flasks at 37° C until crystals were observed. The specimens were centrifuged in a warm apparatus for 10 min at 1,500 r.p.m. and the sediment was immediately examined under the microscope. The

pH of the samples varied from 5.8 to 7.0 and none of them was grossly infected. Crystalline substances were identified and distinguished by their habit, their appearance in polarized light, and their solubility in acetic and hydrochloric acids on the microscope stage. These procedures were found to be sufficient for the range of crystalline substances occurring in urine.

The only crystalline substances observed in these samples of fresh urine were calcium oxalate and one form of calcium phosphate. Other compounds previously described in urine, notably uric acid, ammonium urate, stellar calcium phosphate (calcium hydrogen phosphate, brushite) and magnesium ammonium phosphate, were only seen when the slides or incubated samples were examined several hours after voiding. The calcium oxalate was invariably present as tetragonal dipyramids (octahedra, "envelopes") known to be the dihydrate or weddellite salt. At the limits of our light microscopy (about  $\times 2,000$ ) the calcium phosphate precipitate appeared irregular. It did not extinguish well in polarized light, gave no evolution of carbon dioxide with acetic acid, and though presumably formed of basic calcium phosphate, could not accurately be described as crystalline hydroxyapatite. All the subjects passed one or both of these materials at some time during the day and there was no clear difference between stone-formers and controls in this respect.

Urine samples which contained no crystalline material were next cooled to room temperature and their pH raised to 6.8 by the addition of 0.1 normal sodium hydroxide, in order to observe the formation of crystals. Again, calcium oxalate and calcium phosphate were the only crystalline substances observed to precipitate, although the calcium oxalate now began to assume various habits (hexagon or "tablet", oval or "biscuit"). Both these and later observations in this qualitative study showed no significant differences between the two groups.

The samples treated with sodium hydroxide were then refrigerated overnight at 4° C in order to obtain a fresh crop of crystals. Under these conditions the previously discrete calcium oxalate crystals aggregated, as shown in Figs. 1 and 2, to form fused and semi-fused masses of appreciable size ( $> 100\mu$ ). This was the only point in the study at which true crystal aggregates (as opposed to twinning effects) were noted. No similar phenomenon was observed for the irregular deposits of calcium phosphate. Although the urine state was ill-defined we nevertheless thought that this aggregation might be a stage in the formation of a stone, and a further experiment was performed to check this theory.

Twelve calcium oxalate stones, all predominantly or partly weddellite, were finely ground individually in an agate mortar, using a slow, lateral shearing motion. The powdered samples were taken up in a minimum of dis-

Fig. 1. Calcium oxalate tetragonal dipyramids in early state of aggregation ( $\times 450$ , polarized light).

Fig. 2. Semi-fused mass of calcium oxalate crystals in later aggregation stage ( $\times 200$ , plane light).

Fig. 3. Debris from ground calcium oxalate stone, with (centre) well formed tetragonal crystal ( $\times 200$ , plane light).

titled water and microscopically examined. In each case, against a background of morphologically unrecognizable debris, many roughly shaped but unmistakable calcium oxalate crystals of the tetragonal dipyramidal type were visible (Fig. 3). These crystals were invariably  $5\text{--}10\mu$  in size, that is, of a size comparable with those seen in fresh urine. Recognition in plane and polarized light was supplemented by phase contrast examination, when the crystal edges became visible as dark lines radiating from the pyramidal apex.

These observations suggest that many or most of the crystalline materials hitherto described in urine<sup>3,4</sup> develop after voiding when the urine is left to cool and the pH is allowed to rise. They may therefore be regarded as artefacts. The only crystalline substances consistently found are calcium oxalate and calcium phosphate, but the latter is seen only as irregular deposits with the light microscope. The calcium oxalate crystals are much smaller than those previously described in urinary calculi by Prien<sup>5</sup>, Murphy and Pyrah<sup>6</sup> and others, but the crystals which we observed after grinding a calculus were of a size comparable with those seen in the fresh urine and indistinguishable from them. It is therefore possible that aggregation of crystals is more important in stone formation than crystal growth. We were able to produce aggregation very early outside the body but did not see any aggregates in freshly voided urine. Aggregates have been described in urine by Sengbusch and Timmermann<sup>7</sup>, but in view of the method of collection of their samples it is not possible to decide whether they were present before the urine was voided.

On the present evidence no conclusions can be drawn as to whether the larger crystals found in calculi are

formed solely by the aggregation or by the selective dissolution and reprecipitation of the smaller urinary crystals. What does seem probable is that the initial step in the formation of urinary calculi involves the precipitation from supersaturated solution of the crystalline salts which will eventually form the great bulk of the concretion.

We thank Dr C. K. Anderson for the photographs and microscope facilities.

### Long-term Behavioural Aberration produced in Mice by a Pharmacological Agent

HARMALA alkaloids which are derived from plants all contain a  $\beta$ -carboline moiety. These compounds have been of interest because they are hallucinogenic<sup>1-3</sup>, in addition to possessing other pharmacological properties<sup>4</sup>. Because of the ease of formation of tetrahydro- $\beta$ -carbolines from the reaction of tryptamines and aldehydes in mild, aqueous conditions, they have been suggested to be endogenously formed psychotropic agents and causative factors in some psychoses<sup>5</sup>. In order to investigate further their effect on animal behaviour, and other pharmacological responses, a series of new tetrahydro- $\beta$ -carbolines (tetrahydroharmans) has been synthesized<sup>4</sup>. One of these was prepared by the Pictet-Spengler reaction from 5-methoxytryptamine and pyridoxal (vitamin B<sub>6</sub>). The structure of the compound, 1-(3-hydroxy-5-hydroxymethyl-2-methylpyridyl-4)-6-methoxy-1,2,3,4-tetrahydro- $\beta$ -carboline (compound 1), is shown in Fig. 1. Thus it contains indole, 5-substituted tryptamine,  $\beta$ -carboline and vitamin B<sub>6</sub> moieties combined in one molecule. When compound 1 was injected intraperitoneally into trained rats at dosages useful for behavioural studies of other tetrahydro- $\beta$ -carbolines (1.5–3 mg/kg) all animals were slowly intoxicated and died within 24–48 h.

The toxicity of the compound was therefore examined in less valuable animals (untrained mice). Six male Sprague-Dawley mice (weighing 30–40 g) kept in separate cages were injected with doses of 1.2, 2.4, 4.6, 8, 12 and 14 mg/kg of compound 1 in water. Only the animals at the two larger dosages showed acute responses consisting primarily of hind leg paralysis shortly after injection lasting about 20 min. All animals were alive 48 h later but seemed to suffer a lethargy or catatonia compared with uninjected mice. These six animals were kept in separate cages for several weeks, and at the end of this time they seemed to recover completely and were transferred to

Fig. 1.

cages containing four or five mice, not treated previously with any agents.

The four mice which received 4.6–14 mg/kg (13.6–41.3  $\mu$ mole/kg) reacted identically in this situation. First, there seemed to be a short period of 3–20 min of "induction", when the newly introduced mouse began to exhibit signs of great agitation characterized by trembling and erection of its tail and rapid rotation of it. These traits persisted as long as the treated mouse was in the presence of the others and terminated when it was replaced alone in its cage. After several minutes in the cage with the others, the single mouse began repeated biting attacks on one or two of the other mice, and eventually it was in conflict with every member of the new group. As long as the animals were awake fighting continued. The great intensity of the combat was indicated by several animals suffering from deep bleeding wounds. The animals, when allowed to remain together overnight, were found in the morning with the untreated mice sleeping together and the previously medicated animal sleeping on the opposite side of the 22 cm cage. As soon as they awakened, the intense attacks by the previously treated animal resumed. In several instances the smaller animals of the group died during the fighting. Although, initially, the largest mouse of the group of animals attempted to thwart the aggression of the treated animal, it was eventually dominated in the same way as the others in the group and huddled with them for mutual protection.

The experiment was repeated with another group of six mice taking each animal from a group of its associates, injecting it, keeping it separate, and placing it back in the same cage 24 h later. The same pattern was seen as before, with the injected mice undergoing a dramatic transformation of their behavioural patterns. The mice were removed and kept separately for 3 weeks. On placing each one into a cage containing the group it came from, again there was a high level of aggressiveness and biting attacks by the new animals. In this later experiment six control animals were injected in the same manner with saline and caged separately in the same way as the other mice. After 3 weeks, when they were placed back with their original groups, fighting occurred with only two out of the six control animals. This abated usually within 20 min and the newly introduced animal was then assimilated by the group. With five out of the six animals introduction into the cage was characterized by either intense fighting, great agitation without fighting or polarization from the group where the animal stayed on the opposite side of the cage from the grouped animals; this was especially noticeable during sleep.

When solutions of the carboline were allowed to stand overnight or heated while they were being prepared, all or part of their potency was lost. Examination of these solutions on silica thin-layer or glass chromatography (9 : 1 chloroform-methanol) showed the original xanthrydrol positive spot changing to two new ones. Thus varying degrees of chemical transformation occurred in these instances.

These observations indicate that a long range aberration of the animals' normal behaviour occurred after one injection of compound 1. Explanation of this long-term phenomenon seems to be dependent on the formation of a lesion in the central nervous system. Vitamin B<sub>6</sub> is the co-factor for the enzyme formation of various brain amines<sup>7</sup>. Tetrahydro- $\beta$ -carbolines apparently cross the barrier between blood and brain in animals readily, because they have psychotropic effects. When pyridoxal is reduced in position 4 to desoxypyridoxine, it is converted to the most potent antagonist of that vitamin<sup>8</sup>.

Because compound 1 combines both a tetrahydro- $\beta$ -carboline moiety and a form of pyridoxine where the 4 position is modified, it may be an antagonist of vitamin B<sub>6</sub>, especially capable of crossing the blood-brain barrier. Possibly compound 1 acts through an inhibition of synthesis and complete depletion of an important amine

in some part of the mouse brain which could produce a lesion. The possibility of the involvement of ribonucleic acid cannot be excluded. These results suggest that the tetrahydro- $\beta$ -carboline would be a useful tool for studying the role of vitamin B<sub>6</sub> in the brain or for manipulating concentrations of amines in the central nervous system. It may also be applicable to the production of lesions in specifically localized sites of the brain.

### Crystalline Aflatoxin M<sub>1</sub> from Urine and Milk

Allcroft and Carnaghan<sup>1</sup> and de Jongh *et al.*<sup>2</sup> reported the appearance in milk of a compound related to aflatoxin B<sub>1</sub>, and Allcroft *et al.*<sup>3</sup> showed by thin-layer chromatography and ultra-violet studies that a similar factor appeared in the urine of sheep given mixed aflatoxins. Holzapfel *et al.*<sup>4</sup> isolated the urinary compound and established that it was aflatoxin M<sub>1</sub> (Fig. 1).

That the factor found in milk, which has not hitherto been crystallized, is the same as urinary aflatoxin M<sub>1</sub> has been assumed solely on the basis of chromatography and ultra-violet spectra. We report here the isolation of crystalline M<sub>1</sub> from sheep urine and cows' milk after a dose of mixed aflatoxins.

A 'Holstein' cow was given the equivalent of 80 mg of aflatoxin B<sub>1</sub> daily, contained in rice that had been inoculated with *Aspergillus flavus*, NRRL 2999 (ref. 5). The rice was mixed in the feed but, because the cow refused it, was given by capsule in the third week. The cow succumbed rapidly: her appetite diminished, she developed acute emphysema, and in the fourth week, when her lactation ceased, she was killed. Urine was collected from a ewe and a wether given aflatoxin B<sub>1</sub> (200 and 100 mg, respectively) on rice, which again had to be given by capsule in the fourth week. The ewe died several days later.

Lyophilized milk from the cow (11 kg) was defatted with *n*-hexane and the supernatant from the basket centrifuge extracted with methanol (46 kg, plus 6.5 kg wash). The methanol extract was concentrated *in vacuo* (3 l.); water (200 ml.) was added and then extracted with low boiling petroleum ether. More water (1.7 l.) was added to the aqueous methanol and three chloroform extracts, each of 3 l., were obtained. The residues from the chloroform extracts weighed 14, 1.2 and 0.8 g. Thin-layer chromatography showed that the first two chloroform extracts contained most of the aflatoxin M<sub>1</sub> and so only these were used. A crude residue was obtained from 15 l. of the sheep urine, collected in the fourth week, by extracting twice with equal volumes of chloroform (methanol was added to prevent emulsions) after neutralization with hydrochloric acid.

The purification and isolation of aflatoxin M<sub>1</sub> from both the milk and urine extracts were essentially the same, so only the procedure for the milk will be described. The residue from the first chloroform extract in 0.5 l. of methanol-water (1 : 1, v/v) was extracted with petroleum

ether. The residue from the second chloroform extract in 0.5 l. of fresh methanol-water (1:1) was combined with the defatted aqueous methanol of the first chloroform extract. The resulting 1 l. of methanol-water was extracted with two 200 ml. portions of xylene from which a recoverable amount of aflatoxin  $M_1$  was back-extracted with an aqueous methanol wash. The aflatoxin  $M_1$  was then extracted with two 1 l. portions of chloroform. The residue from the combined chloroform (2.6 g) was chromatographed on a silica gel column developed with chloroform, then successively with 0.5, 1, 1.5 and 2 per cent (vol.) methanol in chloroform. Crystals of aflatoxin  $M_1$  (8 mg) appeared in the eluate after evaporation and were washed with chloroform, followed by methanol. Crystals of aflatoxin  $M_1$  (15 mg) were obtained in a similar way from a column eluate of the urinary extract.

The identity of crystalline aflatoxin  $M_1$  from urine and milk was established on the basis of melting point (310° C, decomp.<sup>4</sup>); ultra-violet spectra in methanol ( $\lambda_{\max}$  357, 265 and 226 m $\mu$ <sup>4</sup>); formation of acetyl derivatives which were indistinguishable by thin-layer chromatography and ultra-violet spectrum and which had the same ultra-violet spectrum as the unreacted material but were separable from it by thin-layer chromatography; crystallography (shape and refractive indices); X-ray diffraction powder patterns (Fig. 2); infra-red spectra (potassium bromide) similar to that of aflatoxin  $B_1$  but showing a hydroxyl signal at 3.430 cm<sup>-1</sup>; and paramagnetic resonance spectra.

The paramagnetic resonance absorption and integral spectra of the isolated compound from urine were taken at 100 Mc/s in dimethylformamide- $d_7$  (DMF- $d_7$ ) and are fully compatible with the structure of aflatoxin  $M_1$  (Fig. 1). The resonances of all protons can be assigned

Fig. 2. X-ray powder patterns of aflatoxin  $M_1$  crystals from milk (upper) and urine (lower).

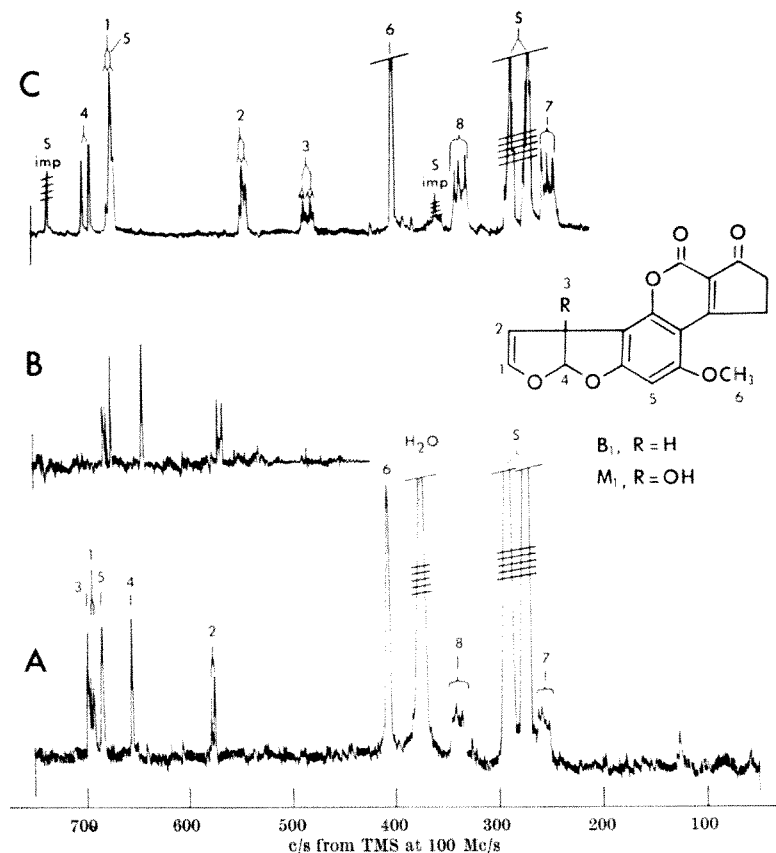

Fig. 1. 100 Mc/s paramagnetic resonance spectra with DMF- $d_7$  as solvent of: A, urinary aflatoxin  $M_1$  at -20° C; B, urinary aflatoxin  $M_1$  at 33° C with trace of TFA vapour added to shift hydroxyl peak; C, aflatoxin  $B_1$  at 31.5° C with TFA vapour added.

(Fig. 1A) by comparison with the spectrum of aflatoxin  $B_1$  (Fig. 1C). The signal assigned to the hydroxyl proton shifted upfield with increasing temperature and disappeared when a trace of trifluoroacetic acid (TFA) vapour was added to the sample as a result of exchange with the carboxyl proton (Fig. 1B). The location of the hydroxyl group is confirmed by the absence in the spectrum of aflatoxin  $M_1$  of any signal corresponding to the three-proton signal of the spectrum of aflatoxin  $B_1$  and by the lack of any coupling of a three-proton to the remaining protons. The spectrum of aflatoxin  $M_1$  from milk in DMF- $d_7$  at 31.5° C was identical to that of urinary aflatoxin  $M_1$  except that the 3-hydroxyl peak was absent because of exchange with traces of water plus acid in the solvent. The DMF used for the aflatoxin  $M_1$  from milk displayed an exchange-broadened (120 c/s) hydroxyl band centred at 540 c/s rather than the sharp peak at 344 c/s observed with the DMF used for the urinary aflatoxin  $M_1$ , which was obtained from another source.

The identification by Holzappel *et al.*<sup>4</sup> of aflatoxin  $M_1$  in the urine was based on comparison of a purified, though not crystalline, urinary concentrate with crystalline aflatoxin  $M_1$  from peanuts. Our identification of urinary aflatoxin  $M_1$  confirms both its structure and appearance in urine.

It has been suggested<sup>1,2</sup> that the milk factor is identical with urinary aflatoxin  $M_1$ , and that aflatoxin  $M_1$  is metabolically derived from aflatoxin  $B_1$  in the mammalian organism. Our results substantiate the first suggestion. As regards the second, de Iongh *et al.*<sup>2</sup> showed chromatographic evidence that administration of purified aflatoxin  $B_1$  to the rat resulted in the excretion in milk of a compound probably identical with the milk factor. Holzappel *et al.*<sup>4</sup> isolated aflatoxin  $M_1$  not only from sheep urine but also from mouldy peanuts. In addition, we have tentatively identified aflatoxin  $M_1$  (by thin-layer chromatography, ultra-violet spectrum and acetyl derivative formation) in the inoculated rice used in our experiments. These observations lead us to suggest the possibility that the appearance of aflatoxin  $M_1$  in urine and milk is related to its presence preformed in the concentrates of aflatoxin  $B_1$  rather than exclusively to its *de novo* synthesis from  $B_1$ . In other pertinent studies in the literature, "mixed aflatoxins" rather than crystalline aflatoxin  $B_1$  have been used. Furthermore, an estimate of aflatoxin  $M_1$  in the dry milk appears to be only 2-3 per cent of the ingested dose of  $B_1$ ; and the excretion of  $M_1$  in the milk is completed within a few hours of ingestion of a  $B_1$  concentrate. The question of preferential excretion of aflatoxin  $M_1$ , if present in extracts of *A. flavus*, into milk had been raised by de Iongh *et al.*<sup>2,6</sup>

Finally, aflatoxin  $B_1$  itself was identified (thin-layer chromatography, ultra-violet spectrum and formation of characteristic derivatives<sup>7</sup>) in the milk of this cow and is estimated at 190 parts per 10<sup>9</sup> in the dried milk, representing only about 0.3 per cent of the ingested dose of aflatoxin  $B_1$ .

### Metabolism of Nuclear RNA in the Rat Kidney after Injection of Folic Acid

WE have previously reported that a single injection of folic acid induces a response in the rat kidney which is characterized by large increases in the synthesis of both RNA and DNA<sup>1</sup>. Twenty-four hours after an injection, the RNA content of each kidney is increased by approximately 50 per cent, although at this time the increase in DNA content is very small<sup>2</sup>.

We have now examined the mechanism of the increase in the synthesis of RNA in the rat kidney during the first 18 h after the injection of folic acid. We measured the incorporation of labelled orotic acid into kidney nuclear RNA *in vivo* and used these results to follow the changes in the rate of synthesis of RNA. In order to ascertain whether the changes were related to a modification of RNA polymerase activity and/or a modification of the efficiency of the DNA template, *in vitro* measurements were made of the "aggregate" RNA polymerase activity of the kidneys<sup>3</sup>.

Male rats were intravenously injected with folic acid (250 mg/kg body weight) as previously described<sup>2</sup>. Injected and control rats were killed at intervals up to 18 h after injection.

**RNA synthesis *in vivo*.** Each animal was intravenously injected with 6-<sup>14</sup>C orotic acid (1  $\mu$ c./100 g body weight) 7 min before it was killed. At each time interval the kidneys from eight animals were pooled and the nuclear pellet prepared as for the "nuclear preparation B" of Widnell and Tata<sup>4</sup>. The pellet was extracted by phenol<sup>5</sup> to obtain the nuclear RNA fraction. The radioactivity of this fraction was determined using a liquid scintillation counter and the RNA content was determined by the orcinol reaction<sup>6</sup>. The results are expressed as c.p.m./mg of RNA.

**RNA polymerase activity.** For each experiment the kidneys from groups of three animals were pooled and the nuclei prepared according to the method of Chauveau *et al.*<sup>7</sup>. A large quantity of the injected folic acid is concentrated in the kidneys (as much as 5 per cent of the total dose per kidney) and is recovered in the form of a precipitate associated with the nuclear pellet. In a preliminary experiment it was found that the presence of large amounts of folic acid was strongly inhibitory to the *in vitro* enzyme activity. In order to separate the nuclei and folic acid precipitate, the pellet was suspended in 2.2 molar sucrose, layered over 2.5 molar sucrose and centrifuged at 40,000g for 15 min in a swinging bucket

rotor: the nuclei remained at the interface whereas most of the folic acid was deposited at the bottom of the tube. The remaining folic acid had only a slight effect on the activity, as shown by the addition of comparable amounts to incubations of "aggregate" enzyme from control rats prepared as previously described for rat liver<sup>8</sup>. The nuclei of control kidneys were treated in the same way. The activity was measured in media of both low and high ionic strength<sup>9</sup>. Because there is no increase in the synthesis of kidney DNA up to 20 h after folic acid injection<sup>10</sup>, in order to facilitate comparison of the enzyme activities the DNA was determined in each nuclear preparation using the method of Burton<sup>11</sup> and the results expressed per mg of DNA. The results shown in Table 1 indicate that there is no increase in the rate of incorporation of labelled orotic acid into nuclear RNA of the kidney up to 6 h after injection of folic acid. By 12 h, however, there is an increase of 75 per cent and at 18 h the increase in specific activity of the isolated nuclear RNA is 90 per cent higher than the control value.

Table 1. EFFECT OF INJECTION OF FOLIC ACID ON THE RATE OF INCORPORATION OF 6-<sup>14</sup>C OROTIC ACID INTO NUCLEAR RNA OF THE RAT KIDNEY *in vivo*

Time after folate injection (h)	0	2	6	12	18
Specific activity (c.p.m./mg RNA)	1,304	1,532	1,218	2,296	2,480

Table 2. VARIATION OF "AGGREGATE" RNA POLYMERASE ACTIVITY OF THE RAT KIDNEY 12 H AFTER FOLIC ACID INJECTION

Source of tissue	Enzyme activity expressed as $\mu$ moles <sup>32</sup> GMP incorporated/mg DNA in 10 min at 37° C	
	"Aggregate" enzyme (low ionic strength medium)	"Aggregate" enzyme (high ionic strength medium)
Normal rats	55	282
Folic acid treated rats	119	461
Ratio	2.16	1.63

Values in the table are the average of three experiments with very similar results. The reaction mixture (0.25 ml.) contains: 160 mmoles *tris* buffer pH 7.0, 4 mmoles MnCl<sub>2</sub>, 8 mmoles 2-mercaptoethanol, 1 mmole each of ATP, CTP, UTP, 1 mmole  $\alpha$ -<sup>32</sup>P GTP and approximately 1 mg DNA of the enzyme extract. High ionic strength medium contains 0.025 ml. of a saturated solution of (NH<sub>4</sub>)<sub>2</sub>SO<sub>4</sub>.

Increases were also found in the activities of the "aggregate" RNA polymerase 12 h after injection of folic acid, as shown in Table 2. The increase of activity at high ionic strength is less than that at low ionic strength. On incubating equal amounts of enzyme extracts from control and injected rats, the average of the values for the two activities was found to indicate that the increase in activity was not related to the disappearance of an inhibitor.

Our results show that there is an early increase in the rate of synthesis of nuclear RNA which is evident several hours before the onset of increased synthesis of DNA in the kidney. This observation agrees with results previously reported for the total RNA during renal compensatory hypertrophy<sup>12</sup> and for the nuclear RNA of regenerating liver<sup>13,14</sup> and of the salivary glands after injection of isoproterenol<sup>15</sup>, and suggests that an increase in nuclear RNA synthetic activity is an essential requirement for the subsequent increase in synthesis of DNA in these systems. It is difficult to compare precisely the kinetics of the increased RNA synthesis *in vivo*, because this is dependent on the specific activity of the labelled precursor pools<sup>14,16</sup> which may differ from tissue to tissue. It appears, however, that both the magnitude of the increases (about double) and the times at which the maximum increases are attained (between 6 and 12 h) are about the same for both regenerating liver and the kidney after folic acid treatment when "pulse" labelling with <sup>14</sup>C orotic acid is used to measure the synthesis of RNA.

The difference in the increase of "aggregate" RNA polymerase activity of the kidney after injection of folic acid measured at both high and low ionic strength was also found in regenerating liver<sup>17,18</sup> and in the prostate gland of castrated rats after injection of androgen<sup>19,20</sup>. The situation was different from that found in rat liver after injection of growth hormone<sup>21,22</sup>, however, when only the "aggregate" RNA polymerase at low ionic strength is increased.

From previous studies it seems that "aggregate" RNA polymerase activity measured at low ionic strength is related both to the enzyme activity and to the "template efficiency" of the DNA, whereas the activity measured at high ionic strength is proportional only to the quantity of active RNA polymerase previously bound to the DNA (ref. 3). Soluble RNA polymerase activity which is also related only to the quantity of active enzyme has been observed in various animal tissues including the kidney<sup>2a</sup>, but unfortunately it has been impossible to measure the changes in activity of soluble RNA polymerase as a result of the loss of the enzyme during the process of removal of folic acid from the nuclei. Thus the increase of RNA synthesis in the kidney after injection of folic acid appears to be related both to an increase in the activity of RNA polymerase and to a better "template efficiency" of the DNA.

We thank Mrs K. Dott and Mr A. T. Buck for excellent technical assistance, and one of us (G. T.) thanks Professor L. F. Lamerton for leave of absence to participate in the work on RNA polymerase carried out in Strasbourg.

### Repression of DNA Synthesis in Mouse Liver Cells after Unilateral Nephrectomy

It is well known that the renal tissue which remains after unilateral nephrectomy is effective in excretion and there is no increase of excreted metabolites in the blood serum a few hours after the operation. Changes in the other body functions (apart from the excretory function of the remaining kidney) after unilateral nephrectomy are still little known. A decrease in the dry weight of the liver<sup>1</sup>

Table 1. INDEXES OF HEPATOCYTE NUCLEI LABELLED WITH TRITIATED THYMIDINE

Series	Time of killing (h after operation)	Index of labelled hepatocytes (%)	
		After nephrectomy	After sham nephrectomy
1	43	0.03 0.10	0.60
2	49	0.10 0.20	2.00
3	67	0.05 0.03	0.60
4	79	0.23 0.09	1.80
5	91	0.30 0.26	0.80

and heart<sup>2</sup> has been observed 1 month after unilateral nephrectomy in mice. This suggests that kidneys take part not only in the regulation of erythropoiesis by erythropoietin but also in the regulation of the growth of other tissues.

I have further investigated this subject in the following experiments. The left kidney was removed from ten C57 mice under ether narcosis, and sham nephrectomy was performed on five of the mice. The animals were divided into five groups with two nephrectomized and one sham operated in each group. The animals were killed 43, 49, 67, 79 and 91 h respectively after nephrectomy. Tritiated thymidine was given intraperitoneally to each animal in a dose of 0.1  $\mu$ Ci/100 g of body weight; the dose was given four times at intervals of 6 h, with the last dose 1 h before the animals were killed. Liver slices were fixed in Carnoy solution and autoradiography was carried out, using liquid P emulsion. After exposure the preparations were stained with haematoxylin and eosin.

Fig. 1. Autoradiography of liver slices from a mouse given tritiated thymidine. a, Mouse at the sixty-seventh hour after unilateral nephrectomy; b, mouse after a sham nephrectomy.

The liver from an animal killed at the sixty-seventh hour after nephrectomy is shown in Fig. 1a; only one hepatocyte and one fibroblast were labelled. In the liver from a sham nephrectomized mouse (Fig. 1b) many labelled nuclei were visible. Indexes of hepatocyte nuclei labelled with tritiated thymidine are given in Table 1. In all cases the indexes of labelled hepatocytes were significantly lower after nephrectomy than after sham nephrectomy. The repression of DNA synthesis in the liver cells after unilateral nephrectomy suggests a regulatory influence of renal tissue on proliferation in other tissues.

I thank Professor L. N. Zhinkin and Dr W. K. Nilowa for their help.

### Strontium-Calcium Selectivity of Alginates

THERE has been considerable medical interest in the ion exchange properties of alginates. Inhibition of the uptake of strontium by rats given doses of sodium alginate has been reported<sup>1-3</sup> and there was a similar experiment with a human adult<sup>4</sup>. The absorption of calcium was not significantly affected. The results were considered to have potential value in connexion with therapy of overdoses of strontium-90 (ref. 5). The effect of two commercial alginates with different chemical compositions, that is, different ratios of mannuronic and guluronic acid residues in the alginate, on strontium uptake in rats was compared<sup>6</sup>. The alginate with the greater content of guluronic acid residues reduced the uptake of strontium from the diet more effectively.

Alginates rich in guluronic acid are known to have more affinity for divalent metals in the ion exchange reactions calcium-sodium, copper-sodium and barium-sodium than more mannuronic acid-rich alginates<sup>7,8</sup>. In the ion exchange reaction between calcium and magnesium, alginates rich in guluronic acid also have been shown to have more affinity for calcium than have alginates rich in mannuronic acid<sup>9</sup>.

The potential therapeutic applications of alginates make their calcium-strontium ion exchange reaction particularly interesting. The ion exchange properties were determined by dialysing 2 ml. of 1 per cent sodium alginate against 50 ml. of a solution containing a mixture of calcium chloride and strontium nitrate. The ionic strengths of the solutions were 0.66, and the equivalent ratio of the two salts in the solution was chosen to give approximately equal amounts of the two cations bound to the alginate. The salt solution was changed three times, and the alginate gels were dialysed thoroughly against distilled water, and finally against 0.1 normal hydrochloric acid (three samples of 20 ml.). The amount of the two cations in the combined acid dialysates were determined by atomic absorption. The results were calculated as the selectivity coefficient

$$k_{\text{Ca}}^{\text{Sr}} = \frac{[\text{Sr}_g][\text{Ca}_i]}{[\text{Ca}_g][\text{Sr}_i]}$$

where  $[\text{Ca}_i]$  and  $[\text{Sr}_i]$  refer to concentrations in the original salt solution and  $[\text{Ca}_g]$  and  $[\text{Sr}_g]$  to the concentrations in the acid dialysates. Two alginate samples prepared from *Laminaria digitata* (Huds.) Lamour. (61.5 per cent and 68 per cent mannuronic acid) and two samples prepared from the stipes of *L. hyperborea* (Gunn.) Fosl. (30.5 per cent and 27.5 per cent mannuronic acid)

Fig. 1. Strontium-calcium selectivity coefficients for alginates and alginate fragments of varying uronic acid compositions.

were used. In addition, two oligouronides with more extreme uronic acid compositions (91 per cent and 8 per cent mannuronic acid, respectively) were investigated. The oligouronides were prepared by partial acid hydrolysis<sup>10</sup>, and their average degree of polymerization was twenty. The results are given in Fig. 1. By extrapolation of the curve the selectivity coefficients of the two homopolymers can be estimated.

The correlation between the selectivity coefficients and the composition of the uronic acid of the alginates is very clear and indicates that the strontium selectivity of the alginates is caused by their content of L-guluronic acid residues. A polyguluronic acid would seem to be the alginate preparation with the most selectivity for strontium compared with calcium. So far, however, no polyguluronic acid has been isolated from brown algae or from other sources. Among the larger brown algae, the stipes of *L. hyperborea* give the alginate with the greatest content of guluronic acid<sup>11</sup>. This was the source of the commercial alginate with a high guluronic acid content used by Harrison *et al.*<sup>6</sup>. Alginates can be separated into fractions with different uronic acid compositions by precipitation<sup>9,11</sup>, but in no case have fractions with more than 75 per cent guluronic acid residues been obtained. Oligouronides with a very high content of guluronic acid residues (85-93 per cent), however, can be prepared by partial acid hydrolysis of alginates and fractionation of the hydrolytic products<sup>10</sup>. When an alginate rich in guluronic acid is used for the preparation, a high yield may be obtained without fractional precipitation of the hydrolytic products<sup>12</sup>.

### Induction of Malate Dehydrogenase by Oestradiol-17 $\beta$ in the Human Endometrium

HISTOCHEMICAL and biochemical investigations of the human endometrium have revealed variations in the activity of a number of enzymes throughout the normal menstrual cycle<sup>1-3</sup>. Marked differences in the concentration and localization of enzymes have been found between endometrial gland cells and stromal cells. It is commonly assumed that these variations in enzyme activity are mediated by oestrogens and progesterone. I thought that a more detailed knowledge of hormone action at a cellular level might be obtained by combining organ culture of human endometrium with quantitative histochemical methods. Maurer has, for example, recently demonstrated the value of organ culture techniques for the study of the effects of steroid sex hormones on target tissues in animals<sup>4</sup>. By the combined techniques I have now detected an increase in malate dehydrogenase activity in the human endometrium stimulated *in vitro* by oestradiol-17 $\beta$ . The increase in enzyme activity occurs mainly in the cells of the endometrial glands and is suppressed by actinomycin D and I think that it is due to the formation of new enzyme.

Regenerative phase endometrium was obtained at routine curettage from five patients with a normal menstrual history. One specimen was obtained on the seventh day of the cycle, three specimens on the twelfth day and one on the thirteenth day. A strip of tissue was immediately divided on removal into four portions. One portion was frozen at  $-70^{\circ}\text{C}$  by the cold tube method<sup>5</sup> and the others were transferred to culture chambers. The tissue was set on lens paper on a stainless steel grid in a silica dish containing Trowell tissue culture medium T 8. Culture was carried out at  $37^{\circ}\text{C}$  in an atmosphere of 95 per cent oxygen and 5 per cent carbon dioxide for 5 h. One culture was used as a control. Oestradiol-17 $\beta$  was added to the second culture at a concentration of  $100\text{ }\mu\text{g/l.}$  ( $3.7 \times 10^{-7}$  moles/l.). The third culture contained actinomycin D at a concentration of  $600\text{ }\mu\text{g/l.}$  in addition to the oestradiol-17 $\beta$ . After culture the tissue was frozen according to the above method and stored in a cryostat for a maximum of 12 h.

Sections of the tissue  $10\text{ }\mu$  thick were prepared in the cryostat with a knife cooled to  $-60^{\circ}\text{C}$  and with the chamber between  $-25^{\circ}\text{C}$  and  $-35^{\circ}\text{C}$ . These were then mounted on warm slides and covered with the histochemical medium without allowing them to dry. Pearse's<sup>6</sup> method was used to determine the malate dehydrogenase, except that 0.05 molar glycylglycine buffer at pH 7.5

Fig. 1. Regenerative endometrium, seventh day, after culture for 5 h with oestradiol-17 $\beta$  and actinomycin D, to show failure of actinomycin to inhibit mitosis. (Stained with haematoxylin and eosin,  $\times$  c. 260.)

Fig. 2. Specimen No. 5. Control tissue after culture for 5 h, showing malate dehydrogenase activity. Nitro blue tetrazolium reduction. ( $\times$  c. 300.)

was used instead of phosphate buffer. Neo-tetrazolium chloride was used as the electron acceptor for quantitative purposes because of the insolubility of the formazan formed from nitro blue tetrazolium. The sections were incubated for 1 h in air at  $37^{\circ}\text{C}$  and afterwards washed in water and dried in air. Five sections were taken from each block for quantitative study. Sections for permanent mounting were fixed in neutral 10 per cent formalin before mounting and some were fixed in Masson's fixative and stained with haematoxylin and eosin for histological examination. From time to time sections were incubated in the medium without substrate and these acted as controls. Formazan was not formed in any of these controls.

The area of the sections was measured and formazan was eluted in 0.5 ml. of 10 per cent *n*-heptanol in tetrachloroethane<sup>7</sup>. The optical density of the eluent was read at  $550\text{ m}\mu$ .

Histological examination confirmed that all specimens were in the regenerative phase of the cycle and showed no abnormal features. Tissue survival during culture was excellent as judged histologically (Fig. 1) and continuing mitotic activity was seen in most cases. The tissue from

specimen No. 4 treated with actinomycin became impregnated with ice crystals during mounting and is not included in the present results (see Table 2).

Figs. 2-4 show the appearances of staining for malate dehydrogenase in a typical specimen. There is a substantial increase in the amount of formazan deposited in the tissue treated with oestrogen and the increase is largely in the gland cells. The changes in the specimen treated with oestrogen are not evident in the other three preparations which have a similar appearance to one another.

Table 1 gives the full results of formazan elution for specimen No. 2 while Table 2 gives the combined results of formazan elution for the series. It can be seen that the results for the tissues treated with oestrogen are consistently almost double those for the control tissues and for the tissues treated with actinomycin D. The specimens from late in the regenerative phase show concentrations of enzyme of the same order while the specimen from seven days shows a much lower concentration.

The techniques used in this investigation provide a rough method of estimating enzyme activity in a heterogeneous tissue. Measurement of the area of a section does not take into account variations of thickness and this should be regarded as a possible source of error. The number of measurements in the series is small, but the results are sufficiently consistent to allow some general conclusions.

Malate dehydrogenase is known to increase in activity throughout the regenerative phase of the menstrual cycle

Fig. 3. Specimen No. 5. Increase in malate dehydrogenase activity after culture for 5 h with oestradiol-17 $\beta$ . Nitro blue tetrazolium reduction. ( $\times$  c. 300.)

Fig. 4. Specimen No. 5. No increase in malate dehydrogenase activity after culture for 5 h with oestradiol-17 $\beta$  and actinomycin D. Nitro blue tetrazolium reduction. ( $\times$  c. 300.)

and reaches a peak early in the secretory phase $^2$ . The results presented here show that a similar effect can be observed when regenerative phase human endometrium is stimulated *in vitro* by oestradiol-17 $\beta$ . One criterion of a successful *in vitro* technique is that known *in vivo* processes should be simulated.

The suppression of the oestrogen effect by actinomycin D suggests that the increase in enzyme activity occurred as a result of the synthesis of new RNA followed by the synthesis of new enzymes. Such a pattern conforms with current theories of enzyme induction by steroid hormones $^8$ . Although no information concerning the detailed mode of action of oestrogens can be derived from these results, the overall pattern of action in the human is shown to be similar to that described for other animals $^9-10$ .

I thank Dr C. G. Paine for his help and encouragement during these investigations.

### Permeability Factors of Rabbit Skin associated with Delayed Vascular Response to Thermal Injury

INCREASED vascular permeability is an important feature of thermal injury, as it is of all inflammatory processes. The phenomenon is often biphasic: the early transient response is mediated by a substance inhibited by antihistamine drugs, while the more intense and prolonged delayed response is mediated by factors which are not influenced by antihistamines. A permeability factor isolated by us from lesions during the delayed response to thermal injury was found to be distinct from previously

described permeability factors which are either proteases (PF/dil, kallikrein), proteins (lymph node permeability factor), or peptides (leukotaxin, bradykinin, kallidin)<sup>1-4</sup>. This communication deals with further purification of the burns permeability factor.

Thirty sites in an area of 10×12 cm on the clipped flanks of albino rabbits (2-2.3 kg) were subjected to 56° C for 20 sec<sup>2,5</sup>. The permeability effects in the burn lesions, and the potency of extracted permeability factors injected intradermally, were measured in terms of exuded dye extractable from the lesions in animals with pontamine blue in the circulation<sup>6</sup>. The delayed response to the heating began within about 40 min, reached a peak in about 2 h and disappeared in 6-8 h. From the extracts of skin acetone powder prepared from 2 h old lesions, pseudoglobulin fractions were prepared with ammonium sulphate<sup>2</sup> and chromatographed. Concentrations of protein were recorded as the absorbancy, *E*, at 280 mμ, and increase of specific permeability was expressed as μg of dye extracted/absorbancy at 280 mμ. Before the test on rabbit skin all samples were dialysed against M/15 phosphate buffer (pH 7.4).

When pseudoglobulin fractions (15 ml.; absorbancy 20-30) in M/15 phosphate buffer (pH 7.4) were desalted through a column of 'Sephadex G-50' medium<sup>7</sup> (with a flow rate of seven drops/min and 6 g effluent fractions collected) one chromatographic peak of absorbing material was obtained, and the potency for increasing the permeability of the effluent fractions clearly paralleled the absorbancy. The mean specific activity of the active fractions was about 3.1.

The active fractions (absorbancy 20-22) were fractionated on DEAE-cellulose (Brown)<sup>8</sup> by successive elution with phosphate buffer of the following molarity and pH: 1/150, pH 6.8; 1/150, pH 7.4; 1/100, pH 7.4; 1/50, pH 7.4; 1/15, pH 7.4; 1/15 plus M/5 sodium chloride, pH 7.4; and finally with molar sodium chloride. The rate of flow was 12 ml./h and 3 g effluent fractions were collected. Of the four absorbing peaks obtained the first three had specific activity of 1.3 (eluted in M/150, pH 6.8), 6.8 (in M/15) and 3.2 (in M/15 plus M/5 sodium chloride). The fourth (in 1.0 molar sodium chloride) was inactive. The materials in the active fractions were designated factors I, II and III, respectively.

The factor II fractions were further fractionated on DEAE-'Sephadex A-50' medium<sup>9</sup> by successive elution with phosphate buffer as follows; 1/50, pH 7.4; 1/30, pH 7.4; 1/15, pH 6.8; 1/15, pH 7.4; 1/15 plus M/5 sodium chloride, pH 7.4; and finally with 1.0 molar sodium chloride. The flow rate was 8 ml./h and 3 g fractions of effluent were collected. There were six absorbing peaks, of which that in buffer, M/50, pH 7.4, was the most potent, with a specific activity of about 73.3.

Also on DEAE-'Sephadex A-50', factor III fractions were eluted by phosphate buffer at pH 7.4 as follows: 1/50, 1/15, 1/15 plus M/10 sodium chloride; 1/15 plus M/5 sodium chloride; and finally with 1.0 molar sodium chloride. The fourth eluate, in M/15 plus M/5 sodium chloride, was active, with a low specific activity of 9.5. This eluate was fractionated on hydroxylapatite<sup>10</sup> by successive elution with buffers at pH 6.8, as follows: M/200 phosphate, 3 M/100 phosphate, 3 M/20 phosphate, 3 M/10 potassium phosphate and 1.0 molar potassium phosphate. The flow rate was 8 ml./h and 6 g effluent fractions were collected. The mean specific activity of the first component (in M/200) was about 74.2. No permeability effect was produced by four other components.

The purified factors II and III gave a positive biuret reaction and behaved as homogeneous substances on electrophoresis and ultracentrifugation. They were non-diffusible and thermostable. They would seem to be a family of peptides.

These observations indicate that the burns permeability factor in the pseudoglobulin fraction is a complex of factors I, II and III. The *in vivo* effects of the burns permeability

factor and of each of the separate factors are long-lasting<sup>11</sup>, and so it seems reasonable to suppose that the delayed vascular permeability response to thermal injury is caused by the combined action of the three factors. The long-lasting effect of the factor distinguishes it from the permeability factors mentioned in the first paragraph, all of which produce only a short-lived increase in vascular permeability on experimental injection. In the same way it appears that the delayed vascular response in the Arthus reaction is mediated by an Arthus permeability factor made up of three similar factors, I, II and III<sup>12,13</sup>.

### Inhibition by Purines of the Production of Fronds in *Lemna perpusilla*

WHILE examining the herbicidal properties of a variety of compounds using a modified duckweed test<sup>1</sup>, we noted that several purine derivatives showed marked inhibition of the production of fronds of *L. perpusilla* growing in a chemically defined medium<sup>2</sup>. In these experiments 10 ml. of sterile Hillman's medium<sup>2</sup> (with sucrose) was added to 1×4 in. test-tubes (capped with Morton stainless steel closures). Dilutions of the test substances were added to the tubes and three fronds of *L. perpusilla* were then added. The inoculated tubes were placed on slanting boards in a room with a constant temperature of 75° F which was illuminated for 14 h each day. The number of fronds in each tube was determined after 3, 5, 7 and 9 days of incubation. Four replicate tubes were started for each concentration of test compound, and the average number of fronds in each tube was plotted in the dose-response curve. The concentration of inhibitor needed to reduce growth to 50 per cent of that of the untreated controls was determined graphically. In these conditions a ten-fold increase in the number of fronds was noted in the control tubes during the 9 days.

Table 1. INHIBITION OF *Lemna perpusilla* BY PURINE

Purine tested	Concentration causing 50 per cent inhibition of frond production (p.p.m.)
Purine	2
Kinetin	2
6-Methylpurine	0.001
6-Chloropurine	10
6-n-Heptylamino purine	> 10
6-n-Amylamino purine	> 10
6-β-Naphthylamino purine	> 10

The data collected in a series of experiments are summarized in Table 1. Purine and kinetin inhibited the production of fronds at 0.1–0.2 p.p.m., and 2 p.p.m. ( $1.5 \times 10^{-5}$  molar) was sufficient to cause 50 per cent reduction in frond production. Kinetin did not stimulate the production of fronds at any concentration tested (0.001–0.2 p.p.m.), and had an inhibitory effect at concentrations greater than 0.1 p.p.m. 6-Methylpurine was even more toxic, 0.001 p.p.m. ( $1 \times 10^{-8}$  molar) causing 50 per cent inhibition, and significant inhibition was noted with 0.00001 p.p.m. 6-Chloropurine was much less effective, 10 p.p.m. being required for inhibition of multiplication of fronds, and the other purines examined had no inhibitory effects at concentrations of less than 10 p.p.m.

The inhibition caused by 6-methylpurine, kinetin, and purine could be reversed by addition of adenine to the growth medium; 2 p.p.m. of adenine completely reversed the inhibition caused by 2 p.p.m. of purine and 0.001 p.p.m. of adenine reversed the inhibition caused by 0.001 p.p.m. of 6-methylpurine.

These experiments show that the production of fronds by *L. perpusilla* is quite sensitive to exogenous purines. 6-Methylpurine may have possibilities as an agent to control duckweed in ponds. It probably acts by interfering with purine metabolism, because adenine is an effective reversing agent.

We thank Dr W. S. Hillman for the culture of *Lemna perpusilla* and Professor F. M. Strong for the kinetin analogues.

## Genetic Variant of Human Erythrocyte Malate Dehydrogenase

MALATE dehydrogenase exists in two distinct forms in a variety of mammalian tissues, one of which is in the cytoplasm as a soluble or supernatant enzyme and the other is tightly bound to the mitochondria<sup>1</sup>. These two forms have different chemical, physical and kinetic properties<sup>2–4</sup> and each has a characteristic electrophoretic pattern<sup>5</sup>. Unlike most tissues erythrocytes possess only cytoplasmic malate dehydrogenase, as would be expected in the absence of mitochondria. This report concerns an inherited electrophoretic variant of erythrocyte (supernatant) malate dehydrogenase which was found in a survey of haemolysates prepared from 2,910 individuals, of whom 1,440 were white and 1,470 were North American Negroes. All were unrelated so far as is known, and consisted of unselected patients and personnel of three Buffalo hospitals. In the family investigations, both haemolysates and leucocyte extracts were electrophoresed.

Haemolysates were prepared by mixing one volume of packed, twice washed red cells with two volumes of water. Leucocyte extracts were prepared by removing the buffy coat with a Pasteur pipette, after which the cells were washed briefly in distilled water and then in saline. The white cells were resuspended in an equal volume of distilled water and subjected to sonication for 1 min.

The haemolysate survey was carried out on horizontal starch gel electrophoresis using a 0.01 molar phosphate buffer in the gel and a 0.2 molar phosphate buffer in the end trays, both at pH 7.0. Good results were obtained both when run at 10 V/cm for 5 h and 4 V/cm for 16 h.

Improved definition of the mitochondrial enzyme was obtained with vertical starch gel electrophoresis in a phosphate-citric acid buffer at pH 7.0 (ref. 5). In each case the gels were sliced horizontally after electrophoresis and the developing solution consisted of 725 mg of DL-malic acid, 5 mg of nicotinamide-adenine dinucleotide (NAD), 5 mg of phenazine methosulphate and 5 mg of MTT tetrazolium in 50 ml. of 0.1 molar phosphate buffer solution at pH 7.0.

Partial purification of the enzyme was obtained by starch block electrophoresis or DEAE cellulose chromatography. For starch block electrophoresis the method was a modification of that described by Kunkel<sup>6</sup>. Starch blocks measuring 75 × 30 × 1.5 cm were prepared in a glass mould. A trough 25 cm long and 0.15 cm wide was cut across the centre of the block. Haemolysate (15 ml.) was placed in the trough after which electrophoresis was carried out at 4° C. A 0.008 molar phosphate citric buffer, pH 7.0, was used and a gradient of 300 V was applied to the block for 20–48 h. To avoid changes in pH on the block, the outer end trays were exchanged approximately every 8 h during the electrophoresis. At the end of electrophoresis 2.5 cm sections were removed from each end of the block and discarded and the remaining 70 cm was cut into 2.5 cm sections and numbered 1–28 from the cathodal end. Each section was eluted in a coarse fritted disk funnel with 7.0 ml. of a 0.008 molar phosphate citric buffer, pH 7.0. The eluates were tested for activity of malate dehydrogenase by spectrophotometric assay<sup>7</sup> and they were subjected to starch gel electrophoresis.

For DEAE cellulose chromatography 10 g of DEAE cellulose was equilibrated with 0.01 molar *tris* hydrochloride buffer, pH 8.2, in a column 2.5 cm in diameter. Haemolysate (5 ml.) was washed into the column and a linear gradient to 0.3 molar *tris* hydrochloric acid, pH 8.2, was used for elution. Fractions (7 ml.) were collected and analysed for malate dehydrogenase activity, and subjected to starch gel electrophoresis.

Eluates from starch block or cellulose chromatography which had been proved to contain only the major normal band or the slowest variant band were concentrated by vacuum filtration to 0.5–1.0 ml. and dialysed in 0.1 molar sodium phosphate buffer, pH 7.0. A 0.5 ml. sample of each concentrate was mixed and subjected to reversible inactivation in acid, a process which involves the dissociation of the enzyme into inactive sub-units and then recombination of the sub-units to yield active enzyme<sup>8,9</sup>. The reactivated enzyme was subjected to starch gel electrophoresis and assay for malate dehydrogenase.

The usual red cell malate dehydrogenase pattern after starch gel electrophoresis consists of a major anodal band and two minor bands which migrate slightly faster and which are very variable in staining intensity (Fig. 1). One variant was found in an apparently normal, healthy Negro female among 2,910 samples from Negroes and Whites. The variant pattern consists of three distinct major bands, one of which corresponds to the normal major band; the other two have slower migratory rates as depicted in Figs. 1 and 2 and in the diagram in Fig. 3. The minor anodal bands are the same for the proposita as for a normal individual. The supernatant leucocyte enzyme also shows the variant pattern, but the mitochondrial pattern is normal, as seen in Fig. 2. The variant pattern was observed in the erythrocyte malate dehydrogenase of the two sons of the proposita but not in that of the daughter or her mother. Her father was not available for testing. Six half sibs of the proposita had the normal erythrocyte malate dehydrogenase pattern.

Concentrated eluates from both starch block and DEAE cellulose columns were found which contained only the slowest moving band of the variant erythrocyte enzyme (Fig. 3, slot 4). Slot 3 contained a similarly isolated and concentrated eluate of the normal enzyme. An untreated mixture of these isolated slow and normal bands was placed in slot 5. The result of a mixture of the same two

bands subjected to the reversible inactivation and recombination procedure is shown in slot 6. Here the intermediate band was created from the fast and slow bands.

This seems to be the first reported genetic variant of human erythrocyte malate dehydrogenase. The three bands suggest that the supernatant enzyme is a dimer, because the random association of two sub-units would be expected to produce such a pattern. The dissociation and subsequent recombination of the slowest moving variant band and the normal band to produce three bands represents *in vitro* support for the dimer hypothesis. Presumably there has been a mutation of the allele which controls one of the sub-units of the molecule. The family and electrophoretic data show that the genetic control of supernatant malate dehydrogenase is autosomal. Although the pedigree does not rule out sex linkage, because the variant pattern is the same in males and females, the mutant

Fig. 1. Photograph of a horizontal starch gel showing the normal erythrocyte pattern of malate dehydrogenase in slot 3 and the variant pattern in slots 1 and 2. In this picture only one of the minor bands is visible, and in the case of the variant it is very indistinct.

Fig. 2. Photograph of a vertical gel in a phosphate-citrate buffer as described in the text. In slots 1 and 2 are erythrocyte and leucocyte preparations from the proposita and in slot 3 is a normal leucocyte extract. The variant pattern is confined to the anodal or supernatant malate dehydrogenase, while the cathodal or mitochondrial malate dehydrogenase is unaffected.

Fig. 3. A diagram of erythrocyte patterns of malate dehydrogenase. In slot 1 is the normal pattern, and in slot 2 the variant. Slot 3 represents a partially purified normal band, and slot 4 the partially purified slowest moving band of the variant. In slot 5 is a simple mixture of 3 and 4, and in slot 6 this mixture following dissociation and recombination of sub-units.

allele could not be on the X chromosome. If it were, the erythrocyte malate dehydrogenase of hemizygous affected males would appear as a single band with the same electrophoretic mobility as the slowest band of the variant pattern. The observation that the mitochondrial malate dehydrogenase is indistinguishable from normal in an individual with a genetic variant of the supernatant enzyme provides additional evidence suggesting that the two cellular forms of this enzyme are controlled by separate genetic loci.

## PHYSIOLOGY

### Further Investigations into the Function of the "Mirror" in Tettigonioidae (Orthoptera)

FROM the calculations of Pierce<sup>1</sup> nearly two decades ago, students of the production of sound in bush crickets have assumed the area of thin cuticle on the right tegmen known as the "mirror" to be acoustically important<sup>2</sup> (Fig. 1). Pierce's attribution of a resonant function to this membrane was challenged by Broughton<sup>3</sup> and Dumortier<sup>4</sup>. Dumortier suggested that the whole tegmen is responsible as an acoustic coupler, not only the mirror. Broughton, working on the decticine, *Metrioptera roeselii* (Hagenbach), found that the frequency spectrum of one individual was not obligatorily changed by coating the mirror with a deadening film of latex. His results have stimulated further work of the same nature on two

members of the Conocephalidae, *Conocephalus discolor* (Thunberg) and *Homorocoryphus nitidulus nitidulus* (Scopoli). Both these animals, like *M. roeselii*, have a well-defined spectrum, but their peak frequencies are at 28 kc/s and 15.5 kc/s, respectively.

The experiments closely followed those of Broughton: recording, applying latex to the mirror, recording, removing latex from the mirror and recording. It was assumed that if the mirror is of acoustic importance latex would (a) lower general intensity and (b) change any natural frequency of vibration. In contrast to Broughton's experiments, however, the latex was not confined to the mirror membrane alone but often covered part of the frame of more or less heavily sclerotized veins surrounding it.

Application of latex in *C. discolor* spread the spectrum over a wider range of frequencies and in most cases caused the peak frequency to occur higher than that of the un-

operated animal (Fig. 2), although in some it was below and in even fewer cases it remained the same. The peak frequency in *H. n. nitidulus* was lowered. While intensity could not be measured in absolute terms it was found to be usually lower for both species.

If the mirror membrane alone were responsible for the amplification of certain frequencies by resonance, to produce a peak in the spectrum, then this property should be modified by the application of the relatively thick film of latex. I suggest that the touching of the frame in my experiments (and perhaps in some of Broughton's) may have been the operative factor in disturbing the spectrum. This implies that the frame is of primary importance in sound production and the mirror membrane of secondary importance (a finding amply confirmed by more recent work on African material).

This work was carried out with the aid of a grant from the French Government at the Laboratoire de Physiologie Acoustique, I.N.R.A., C.N.R.Z., Jouy-en-Josas, S. et O., France, during 1964-65. I thank Dr R.-G. Busnel and Mr W. B. Broughton for their direction of this work, and Mme M. C. Busnel, Mr B. Dumortier and Dr W. Loher for their advice and criticism.

### Gastrin-like Effects of Cholecystokinin-Pancreozymin

WE have studied the effects of "pure" cholecystokinin-pancreozymin (CCK-PZ, kindly supplied by Professor Jorpes) on the human stomach and pancreas, comparing them with the response of these same viscera to a synthetic gastrin-like peptide (a tetrapeptide made by Leo, 10 µg/kg of body weight inducing a maximal response when given subcutaneously).

In all our experiments, the CCK-PZ was given intravenously at the constant rate of 2 Crick-Harper-Raper units/kg body weight/h. The gastrin analogue was given in a similar manner at the rate of 0.5 µg/kg body weight/h. Responses are submaximal at these concentrations.

CCK-PZ induces an acid response in the resting stomach, increasing both the volume and the concentration of the acid and leading to a steady level of secretion (average 12 m.equiv./h) in about an hour. A very similar response was obtained with the gastrin analogue (average 14 m.equiv./h). In both instances a rise in the hydrogen ion concentration was accompanied by a fall in sodium ion concentration.

When both substances were given together at these rates, the one on a background infusion of the other, whether the analogue preceded or followed the CCK-PZ, the acid response of the stomach showed an additive effect with no evidence of potentiation (average 16.5 m.equiv./h). Thus the arithmetic summation of their separate effects is much greater than their combined effect, suggesting a non-linear relationship in their additive effect at submaximal stimulation.

On the pancreas, both substances induced a similar pattern of output of amylase and trypsin.

We feel therefore that CCK-PZ displays gastrin-like effects. It may well be that CCK-PZ and not gastrin accounts for the gastrin-like activity found in extracts of duodenal mucosa. The similarity of action of these two hormones suggests that they may have important amino-

acid sequences in common. The confirmation or refutation of this suggestion will have to await the detailed chemistry of CCK-PZ. The work carried out at the Caroline Institute by Professor Jorpes and Dr Mutt<sup>1</sup> seems to support this point of view, however, because the two compounds have been shown to have C-terminal sequences in common.

### Cerebellum of Mormyrids

In teleost fishes the cerebellum is well developed and consists of two principal parts: the corpus cerebelli and the valvula cerebelli. The former is massive and usually arches backward; the latter is a pouch-like structure which projects forward under the tectum in the mesencephalic ventricular cavity. It has long been known<sup>1,2</sup> that in one group of teleosts, the Mormyrids, the cerebellum attains amazing dimensions. In these forms the valvula consists of an intermediate part and two lateral lobes, and it is the latter which has greatly hypertrophied. These lobes have grown out of the ventricle of the mid-brain, to become superficial structures which cover all other parts of the brain. Fig. 1 shows that the lateral lobes consist of an arched and folded basal layer on which are numerous small and regularly arranged ridges. The intermediate part of the valvula is composed of two lobules which are situated in front of the corpus. The corpus cerebelli itself is bent forward and is of average size (Fig. 1).

The relationships of the fibre tracts<sup>3,4</sup> suggest that the hypertrophy of the valvula in the Mormyrids is related to the high degree of development of the lateral line system, which to a large extent has become transformed into an electroreceptor organ<sup>5,6</sup>.

Microscopically both corpus and valvula contain the three characteristic cerebellar layers: granular, Purkinje and molecular<sup>1,2</sup>, but it is important to note that the granular layer does not extend into the valvular ridges. The latter contain a thin, central fibre zone, on either side of which are found a Purkinje and a molecular layer (Fig. 2). The Purkinje layer also contains medium-sized cells. The molecular layer of corpus and valvula shows characteristic "stripes" perpendicular to the surface (Fig. 2). This so-called palisade pattern has been ascribed to the orientation of the glial fibres<sup>1,2</sup>.

The fibre connexions of the Mormyrid cerebellum have been extensively studied by the Weigert method<sup>3,4,7</sup>, but little attention has been paid to its constituent neurones. We studied serially sectioned brains of *Gnathonemus petersi* and *Petrocephalus bovei*, which were stained according to the Bodian and the Golgi rapid methods. The Golgi material showed that the Purkinje cells in the

corpus and in the intermediate part of the valvula are large and possess a widely spreading dendritic tree, which, as in other teleosts<sup>2,8</sup>, is clearly oriented in the sagittal plane. The initial dendritic branches tend to spread parallel to the surface of the cerebellum. From these primary dendrites issue numerous branches which eventually, after some bifurcation, ascend parallel to each other towards the external surface (Fig. 3). These parallel dendrites are studded with numerous tiny projections and confine themselves to the molecular layer. The Purkinje cells in the lateral lobes of the valvula are smaller than those in the central parts of the cerebellum, but are also provided with straight dendrites. The typical palisade pattern of the molecular layer of the Mormyrid cerebellum is clearly derived from the Purkinje cell dendrites. This vertical orientation of the Purkinje dendrites has not been reported in other teleosts<sup>2,8</sup>, nor in any other group of vertebrates<sup>9</sup>. Sections through the molecular layer, parallel to the cerebellar surface, revealed, furthermore, that in corpus and valvula the Purkinje dendrites are arranged in regular rows (Fig. 4). In the intermediate part of the valvula the parallel fibres are coarse and

Fig. 5. Tangential section through the molecular layer of the intermediate lobe of the valvula. The transversely cut Purkinje dendrites are separated by bundles of parallel fibres.

distinctly impregnated. In this region bundles of parallel fibres alternate with the rows of Purkinje dendrites (Fig. 5). (The granular cells, the axons of which give rise to the parallel fibres, resemble in every respect those of other teleosts<sup>2,8</sup>.)

In the lateral lobes of the valvula the parallel fibres pass directly from the granular layer into the molecular zone, and pass straight to the top of the ridges (Fig. 2). There is no bifurcation. The dendritic trees of the Purkinje cells are oriented perpendicular to the direction of the parallel fibres. It is noteworthy that the cerebellum of birds and mammals shows a transversely oriented folding, whereas the valvula of Mormyrids, judging from the orientation of its parallel fibres and Purkinje dendrites, is folded sagittally. Also remarkable is the fact that the most basal parts of the two cell layers of each valvular ridge contain a row of large cells, the perikarya of which are enveloped by a conspicuous axonal plexus. Two of these elements are visible in Fig. 2. Golgi preparations have shown that the dendrites of these cells extend into the molecular layer but are both thinner and more widely spaced than those of Purkinje cells. The destination of their axons has not yet been determined.

### Monolayer Films of Retinal<sub>1</sub> and the Effects of Light on Them

SEVERAL stereoisomers of retinal<sub>1</sub> (vitamin A<sub>1</sub> aldehyde) are known and their interconversions can easily be promoted by the action of light<sup>1</sup>. The photoconversion of 11-cis to all-trans retinal<sub>1</sub> takes place with the highest efficiency<sup>2,3</sup> and is involved in the first step of the visual process<sup>4</sup>. Studies of vitamin A and its derivatives have suggested that their surface-active properties are closely related to their physiological functions<sup>5,6</sup>. The purpose of the present investigation was to study the properties of monolayer films of all-trans and 11-cis retinal<sub>1</sub> at air-water interfaces, and to determine the effect of light on the films.

Vitamin A oil (15 × 10<sup>6</sup> unit) was obtained from Riken Vitamin Oil Co., Ltd. All-trans and 11-cis retinal<sub>1</sub> were prepared by a modification of Wald's method<sup>7</sup> and re-

crystallized three times from light petroleum ether. The spreading solutions were prepared by dissolving 3 mg of the respective retinal<sub>1</sub> in 10 ml. of ethanol. The solutions were spread on a clean surface of water by means of a micrometer syringe. Surface pressures were measured for various film areas at room temperature using the hanging plate method.

To minimize oxidation of retinal<sub>1</sub>, the measurements for every force-area curve were completed within 20 min of spreading the solution. For the radiation experiments a 500-W iodine lamp, placed 45 cm from the surface, was used. The light passed through a 10-cm thick water cell to avoid heating the films. Surface pressures were measured before and after irradiation, and the area of the film was held constant at 15 × 14.5 cm<sup>2</sup>. All experimental procedures were carried out under a dim red light.

Fig. 1 shows force-area curves of all-trans and 11-cis retinal<sub>1</sub>. Both isomers give liquid expanded films, that of the 11-cis isomer being more expanded than that of the all-trans. The collapse pressures and limiting areas of each molecule of the isomers are shown in Fig. 1. The 11-cis isomer has a larger limiting area and lower collapse pressure than the all-trans one.

Retinal<sub>1</sub> has a bulky lipophilic β-ionone ring attached to a side chain with four conjugated double bonds and terminating in a hydrophilic aldehyde group. The side chain of the all-trans isomer is considered to be flat and straight, while that of the 11-cis one is bent and twisted at the central carbon atom<sup>1</sup>. The relatively straight and flat form of the all-trans isomer allows a closer and more ordered packing on the water surface than with the cis-isomer. The intermolecular forces, which make the film able to withstand the increasing lateral compression, would therefore be stronger than in the other case.

When all-trans and 11-cis films were irradiated, changes were observed in the surface pressures required to keep the film area constant. The changes were maximal after irradiation for 30 sec. In Fig. 2 the changes (percentage increase or decrease) in the surface pressure of films after irradiation for 30 sec are plotted against the initial surface pressure. The surface pressure of the film of all-trans retinal<sub>1</sub> increases in the region below 9 dynes/cm, changes little between 9 and 12 dynes/cm and decreases in the region above 12 dynes/cm. The increase of the pressure on irradiation may be explained by supposing that any other isomers formed will tend to expand the film, or

Fig. 1. Force-area curves of all-trans and 11-cis retinal<sub>1</sub>. Curve 1, all-trans retinal<sub>1</sub>; curve 2, 11-cis retinal<sub>1</sub>. The curves show that all-trans and 11-cis retinal<sub>1</sub> have collapse pressures of 16.1 and 13.8 dynes respectively, and limiting areas of 55.7 and 41 Å<sup>2</sup>/molecule respectively.

Fig. 2. The changes (percentage increase or decrease) in the surface pressure of films of retinal, after irradiation for 30 sec. Curve 1, all-trans retinal; curve 2, 11-cis retinal.

because the area of the film is kept constant, to increase the surface pressure. The decrease in pressures at regions above our initial pressure of 12 dynes/cm could be caused by the squeezing of some part of the retinal<sub>1</sub> out of the film. Conversely, irradiation of the films of 11-cis retinal<sub>1</sub> results in decrease of surface pressure. This similarly may be explained by supposing that the 11-cis isomer is photoisomerized to the lower pressure all-trans one. These properties of retinal<sub>1</sub> films contrast with those of other vitamin A derivatives (our unpublished results).

The change of molecular packing in the film may also be expected to occur in the native physiological membrane when conformational change of the retinal<sub>1</sub> molecule occurs. The molecular packing of rhodopsin in rod outer segments is not well known and the orientation of 11-cis retinal<sub>1</sub> in the membrane is still more obscure. It is probable, however, that the retinal<sub>1</sub> moiety of the rhodopsin molecule exists in the lipid-rich part of the disk-like membrane in the rod outer segment, because retinal<sub>1</sub> is itself a member of the lipid family. Photoisomerization of the retinal<sub>1</sub> would affect the permeability of the membrane, or at least the conformation of the rhodopsin in that membrane<sup>8-10</sup>. Further experiments are in progress along this line.

## Pituitary-Adrenal Regulation of Ceruloplasmin

INVESTIGATIONS of the effect of sex hormones on copper metabolism in man and animals have shown a sharp rise in ceruloplasmin after hormone injection<sup>1</sup>; however, the mechanism of this elevation has not previously been discussed. Hormonal control of the synthesis of RNA has been demonstrated (reviewed by Davidson<sup>2</sup>), and other investigations have shown that both testosterone and oestradiol can bind to DNA and stimulate RNA synthesis<sup>3</sup>. Ceruloplasmin is a protein and as such depends on RNA synthesis for its production. Molecules which act as inhibitors or stimulators of RNA synthesis could therefore control ceruloplasmin production.

In this laboratory, studies of the effect of copper metabolism on the rat have shown that hypophysectomy and bilateral adrenalectomy cause a significant rise in concentrations of ceruloplasmin. In contrast, ACTH administered to intact animals caused a significant decrease in the concentration of ceruloplasmin, as did corticosterone given to adrenalectomized rats. Correlating these findings with recent reports on factors regulating RNA, we have attempted to discover a mechanism to explain the influence of hormone on ceruloplasmin.

Hypophysectomized rats (Hormone Assay) were purchased at 30 days of age and raised to maturity on 'Metrecal', 'Purina' laboratory chow, wheat and water. The remainder of the animals were adult Wistar strain rats, fed 'Purina' laboratory chow, wheat and water. Bilateral adrenalectomy was performed by the trans-abdominal approach via midline incision. After surgery, the animals were continued on the normal diet supplemented with 5 per cent dextrose in saline, and experiments were begun two weeks later.

Blood was drawn by cardiac puncture into a heparinized syringe after the animals had been lightly anaesthetized with sodium pentobarbital (2.5 mg/100 g). Plasma ceruloplasmin concentrations were determined by the method of Houchin<sup>4</sup>, which measures the oxidase activity of the enzyme. Plasma blanks were used with each determination. Oxidase activity was converted to mg/100 ml. ceruloplasmin by multiplying optical density times 157, the constant we have determined for the rat.

Fig. 1. Concentration of ceruloplasmin for the four groups studied. There were twelve animals in each group. The bar represents the mean and the centre line indicates standard deviation.

Fig. 2. Concentration of ceruloplasmin in the adrenalectomized animals which received the supplements indicated below each bar. Each supplement was given for 15 days to twelve animals. The bar shows the mean and the centre line indicates standard deviation.

ACTH in gelatine, 10 IU per day, was administered subcutaneously to intact animals for 15 days. The controls received 0.1 ml. gelatine per day. The ceruloplasmin concentrations for hypophysectomy, adrenalectomy, ACTH, and controls are shown in Fig. 1. Injections of ACTH significantly decreased the concentration of ceruloplasmin ( $P < 0.01$ ), while hypophysectomy and adrenalectomy significantly increased it ( $P < 0.01$ ).

To substantiate the findings of the first experiment, we studied groups of adrenalectomized rats given 0.1 ml. gelatine/day, 10 IU ACTH in gelatine/day or 2.5 mg corticosterone/day, for 15 days (Fig. 2). The ceruloplasmin concentrations of the groups treated with gelatine and ACTH showed no significant difference ( $P > 0.05$ ) but the ceruloplasmin of the animals treated with corticosterone was significantly lower ( $P < 0.01$ ) than either of the other groups.

Extirpation of the adrenal glands may have removed an inhibitor of ceruloplasmin synthesis as suggested by the higher concentration of ceruloplasmin in the adrenalectomized rats. ACTH administered to the intact animal caused a decrease in ceruloplasmin but brought about no change in the adrenalectomized animals. Corticosterone provoked a decrease in ceruloplasmin when administered to the adrenalectomized animals, indicating that the adrenal glands, mediated by the pituitary, play a key part in maintaining ceruloplasmin concentrations.

Steroid hormones alter the synthesis of protein by acting at the transcription level—RNA synthesis<sup>5</sup>. This would imply that the concentration of circulating steroids could influence the concentration of ceruloplasmin. During investigations of copper metabolism in the neonatal rat, we have found that the concentration of ceruloplasmin is low until the twentieth day (0–15.0 mg/100 ml.), and thereafter rises to adult concentrations. In comparison, Halmeyer has shown the concentration of circulating corticosterone in the neonatal rat to decrease from birth until adulthood. On the first day the level is 17.4  $\mu$ g/100 ml., and decreases to an adult level of 3.45  $\mu$ g/100 ml.<sup>6</sup> This indicates an inverse relationship between the concentrations of corticosterone and ceruloplasmin.

The concentrations of ceruloplasmin in the hypophysectomized animals corresponded well with the proposed

mechanism. Without pituitary stimulation, the steroid concentration was lower than normal, which allowed a rise in ceruloplasmin. Because the adrenals were intact, however, the ceruloplasmin did not rise to the high concentrations found in the adrenalectomized animals.

These results indicate the importance of the pituitary-adrenal axis in regulating the concentration of ceruloplasmin. By controlling the level of circulating hormones, the pituitary-adrenal system monitors the production of protein at the site of RNA synthesis.

## Thermal Conductivity of Normal and Infarcted Heart Muscle

ONE of the curiosities of pathology concerns the nature of infarction. Why, when heart muscle dies as part of the total death of an animal, does it produce a histological picture which we term normal, yet when it dies locally in the midst of functioning muscle as a result of a coronary occlusion, it produces a totally different picture called "infarction"?

The present work is not directly concerned with histology, but it does present another physical parameter—thermal conductivity—which is different in normal and infarcted muscle.

Thermal conductivity of heart muscle was measured using a heat exchange method and internal calorimetry<sup>1</sup>. The probe was inserted in the muscle mass of the anterior wall of the left ventricle of the dog or the monkey. This records the temperature increment produced by a current of 0.115 amp<sup>1</sup>. In an infinite mass of muscle the relation between thermal conductivity,  $k$ , and the temperature increment,  $\theta$ , is given by Carslaw's relation  $I^2R = 4\pi r\theta K$ , where  $I$  is the fixed current referred to here,  $R$  is the resistance of the heater,  $r$  is a constant, being the radius of the thermodynamically equivalent sphere. The relation can therefore be re-expressed as  $k = F/\theta$ , where  $F$  is an instrumental constant.

In the present work,  $F$  was determined for each instrument used by fusing the probe into a mass of 10 per cent gelatine in water gel (200 ml.) and determining  $\theta$ . Grayson<sup>1</sup> showed the thermal conductivity of such a gel to be  $12.2 \times 10^{-4}$  e.g.s.u. Accordingly  $F$  could be easily determined.

Thermal conductivity for the heart under observation was obtained by implanting the heated thermocouple during life. The animals were killed and the hearts removed. The section of the ventricle with the heated thermocouple *in situ* was embedded in a mass of 10 per cent gelatine in water gel. The thermal conductivity of such a gel has been shown to be  $12.2 \times 10^{-4}$  e.g.s.u.<sup>1</sup> which approximates to that of a normal protein tissue, and so this procedure minimized the effects of any slight heat losses across the gel-muscle interface.

The results are given in Table 1. It will be seen that the scatter for normal heart muscle is slight and that the figures obtained,  $12.1 \times 10^{-4}$ , approximate closely to those normally quoted for skeletal muscle<sup>2</sup>.

Table 1. THERMAL CONDUCTIVITIES RECORDED FROM HEARTS EMBEDDED IN 10 PER CENT GELATINE/WATER GELS. MEAN TEMP. = 23° C

Normal and infarcted dogs—the difference of the means is highly significant ( $P < 0.001$ )

Normal dog	Infarcted dog Time after ligation	Infarcted monkey Time after ligation
12.1	3 min	11.9
12.2	1 h	7.9
12.2	2 h	11.3
11.6	3 h	9.4
12.2	3 h	11.0
11.8	3 h	10.5
11.4	4 h	10.2
12.8	5 h	10.7
12.2	6 h	10.3
11.9	7 h	8.9
12.2		
Mean 12.1 ± 0.2	10.2 ± 0.4	10.3

Table 1 also gives results for heart muscle removed from the animal at varying periods following occlusion of a coronary artery. In all, evidence of infarction was present; electrocardiograph records before death, macroscopic evidence post mortem and usually histological confirmation. Table 1 shows the thermal conductivity findings. There is an early change and in all cases the thermal conductivity was lower than for normal muscle, the mean value being  $10.2 \times 10^{-4}$  c.g.s.u. for the dog and  $10.3 \times 10^{-4}$  c.g.s.u. for the monkey.

The physical significance of these findings is by no means clear. One suggestion which was considered was that they reflected alterations in the water content of the infarct. Direct measurement of water content was not possible, but relative density was measured by a flotation method. Small portions of muscle were placed in water, in which they sank. A solution of ferric chloride having a relative density of 1.4 was added until the muscle just floated. The procedure was then reversed—beginning with ferric chloride and adding water until the muscle just sank. The density of the solution was measured directly with a hydrometer. The mean relative density for normal heart muscle was 1.06, an identical figure to that quoted for frog skeletal muscle<sup>2</sup>. The mean relative density for infarcted muscle was also 1.06. This suggests that the explanation for the change in thermal conductivity in infarction has a more complex basis than a simple alteration in water content.

### Dermal Photosensitivity and the "Hen and Egg" Problem

GREGORY<sup>1</sup> has viewed the evolution of the visual sense as a "hen and egg" problem involving eyes and brains. It is only reasonable to infer that eyes and brains have mutually exerted evolutionary pressures, but setting aside the somewhat arbitrary distinction between the two, because some eyes incorporate part of the integrative mechanism, partnership between an eye (whether of the simple or compound type) and an integrative apparatus is not the only prescription for a successful photosensory system.

Unfortunately Gregory overlooks the so-called dermat-optic sense which has been widely, repeatedly and successfully exploited in the course of evolution. Although its manifestations have long been known and several times reviewed<sup>2-4</sup>, their implications have been repeatedly

overlooked in considering the evolution of photosensory systems<sup>5</sup>.

Much that has recently been revealed concerning the dermal light sense is directly relevant to Gregory's thesis and initially there appears to be no difficulty in matching his ideas of primordial pattern touch with the development of a diffuse photosensitive surface, which in echinoids such as *Diadema* extends over the whole skin. Integrative centres are already there but eyes are not. The existence of such a photosensory system blurs, but by no means invalidates, Gregory's sharp distinction between photic and tactile or chemo-sensory systems. Thus light not only signals distant events for computation; in some echinoids it also acts as a nociceptive stimulus, signalling an environmental state that causes the animal to cover itself with a pattern of opaque objects corresponding with the pattern of light that falls on the skin<sup>6</sup>. Initially such diffuse photosensitivity appears wholly primitive and a fulfilment of the premise that the first eyes were merely photosensitive areas of skin from which more successful photosensory systems were developed by concentrating and elaborating the photoreceptive areas and their attendant nerve pathways and centres. It is widely assumed that in this process the dermal light sense was left behind as an evolutionary survival. Such a view is over-simplified, because optic and dermatoptic sensory systems may not only co-exist, fulfilling complementary functions<sup>7,8</sup>, but either one or both may be elaborated in accordance with evolutionary potentiality or environmental needs.

Consideration of recent work on bivalves and echinoids is salutary in this connexion. An impressive photosensitivity may be attained without eyes<sup>9</sup> and sophistication may appear not only in the integrative mechanisms associated with the diffuse photoreceptive surface but also in attendant photomechanical pigment movements and light scattering elements<sup>3,10</sup>.

Experimental analysis<sup>9,11,12</sup> has revealed that in these animals the so-called "dermal" photoreceptors are nerve elements devoid of obvious structural adaptation at the microscopic level. Moreover, search for the anticipated sub-microscopic structural differentiation has so far yielded nothing unequivocal<sup>8,13</sup>, though studies of the spectral sensitivity<sup>9,14</sup> and pigmentation of the photosensitive nerve have been more rewarding<sup>15</sup>.

Neural photoreception and its potentialities are therefore to be reckoned with. Its importance is indicated by the means which have been evolved to eliminate what are presumably disadvantageous manifestations, by screening photosensitive nerve with pigment<sup>16</sup>, or by elaborate covering behaviour<sup>6</sup>. The importance is more strikingly revealed in the echinoid *Diadema* where neural photosensitivity has been turned to great advantage. Here light and shadows falling on the skin with its underlying felt of photosensory nerve elicit vigorous movements of the poisonous spines. The parameters of the response depend not only on those of the photic stimulus, but also on integrative and computing activity in superficial and deeply seated nerve centres<sup>17-19</sup>.

The changes in the intensity and pattern of lighting signal the distant events prescribed by Gregory, such as the arrival or movement of a predator, against which the formidable armament of spines is directed. But all this is done without eyes. Moreover, the nervous interaction involved may enhance the perception of movement and contrast<sup>10,20</sup>. There can be no doubt about its effectiveness, judging from the elaborate means of assailing the defences evolved by a predator *Cassia*, the helmet conch, which resorts to spraying the photosensitive skin of its victim with a salivary neurotoxin<sup>21</sup>.

The same sentient surface responds to touch, but the events which follow and the neural pathways involved are different<sup>21,22</sup>. The condition is therefore not primitive in the manner envisaged by Gregory whereby photic stimuli are mediated by the touch neural system.

Shadow reactions are widespread among bottom-dwelling organisms so that recent studies of the dermal light sense have added a new dimension to the significance of photic "off responses", which are now revealed not only as an endowment associated with complex eyes<sup>20</sup> but also as the basis of a widespread characteristic behaviour that may be essential for survival<sup>21</sup>.

Any speculation concerning the evolution of visual systems must therefore take into account what has been achieved by the use of photosensitive nerve and an integrating system, much of which may remain spread out over the entire body surface.

### Habituation of the Crayfish Escape Response during Release from Inhibition induced by Picrotoxin

If the more posterior segments of the crayfish body are disturbed, it will often escape by darting backwards. This escape manoeuvre, in which the appendages are thrust forward and the tail is flexed, is mediated by two lateral giant axons which lie dorsolaterally in the nerve cord<sup>1</sup>. A most intriguing aspect of the reflex is its extreme lability; it invariably fails if an attempt is made to elicit it repeatedly (unpublished results of Krasne and Woodsmall). It is this phenomenon, so reminiscent of habituation in higher forms, which concerns us here.

The escape reflex can be elicited from the isolated crayfish tail by a single shock to one of the segmental nerves which carry sensory fibres to the central ganglia. This response, like that of the intact animals, fails as a result of repeated stimulation. A more direct expression of the same events can be obtained by measuring the transmembrane potential of the lateral giant fibre which lies on the side of the stimulated nerve. An intracellular micro-pipette inserted near the point where the fibre sends a large process into the neuropile of the stimulated ganglion will record a long depolarization (Fig. 1A) each time the segmental nerve is stimulated with a brief (0.1 msec) current pulse. The depolarization can be divided arbitrarily into three components (Fig. 1A:

alpha, beta and gamma). Action potentials which propagate and cause the escape movements arise from the beta component when it exceeds about 7 or 8 mV depolarization at the recording electrode (Fig. 1B). When the segmental nerve is stimulated more often than about once a minute, however, the beta and gamma components show marked decrements which bring the depolarizing response below the threshold for spike initiation (Fig. 1B and C). Direct electrical stimulation of the giant axons as often as once each second elicits tail flexion reliably. The failure of the reflex with repetitive stimulation at the frequencies reported here (1–12/min) is therefore essentially the result of the lability of the beta component of the sensory-evoked response.

The mechanism underlying this lability is an open question. It has been popular to suggest that habituation, at least in higher forms, is caused by active suppression by growing inhibition as opposed to failure of synaptic efficacy as a result of repetitive use<sup>2–7</sup>. This view has been engendered mainly by evidence that recovery (or protection) from habituation can be caused by drowsiness<sup>8</sup>, presentation of novel stimuli (dishabituation)<sup>9</sup>, reduction in intensity of the stimulus to which habituation has occurred<sup>6</sup>, barbiturate anaesthesia<sup>2</sup>, and ablations of various neocortical<sup>3,9</sup> and brain stem<sup>2</sup> structures in mammals or of the vertical lobes or inferior frontal system in octopus<sup>10</sup>. Such evidence, although certainly suggestive,

Fig. 1. Intracellular responses of lateral giant fibres to ipsilateral second root shocks at the level of the third or fourth abdominal ganglia. The nerve cord is exposed dorsally and left *in situ*. A, B, and C are from different preparations; D and E are from a single preparation. In each case the stimulus voltage was held constant during the experiment. (A) A typical response with the normal components labelled. Calibration: 10 mV and 25 msec. (B) Superimposed responses to the first, second, third, and fifteenth shocks at a rate of 1/min in a rested preparation. Spikes arise from the rising limb of the beta component of the first two responses. Calibration: 25 mV and 10 msec. (C) Superimposed responses to the first, second, and twenty-ninth shocks at a rate of 1/5-7 sec. The stimulus intensity was set low enough to avoid reflex induced spikes. Both beta and gamma but not alpha components suffer decrements. Calibration: 10 mV and 25 msec. (D1) Superimposed responses to the first, second, and eighth shocks at a rate of 1/5-7 sec. The stimulus voltage was adjusted so that the beta component did not evoke a spike. (D2) Response after a 5 min rest. Calibration: 10 mV and 10 msec. (E1) Superimposed responses to the first, second, and eighth shocks at a rate of 1/5-7 sec applied 62 min after replacing normal van Harreveld's solution with  $10^{-4}$  molar picrotoxin in van Harreveld's solution. (E2) Response after a rest of 5 min. Calibration: 10 mV and 10 msec.

by no means demands the postulation of augmenting inhibitory processes as the cause for habituation<sup>11</sup>.

A relatively direct evaluation of the role of inhibition in the present case is made possible by the action of the drug picrotoxin on the crayfish nervous system. The drug is a potent convulsant<sup>12,13</sup> and its specific effect has been examined at the crayfish neuromuscular junction<sup>14</sup>, cardiac ganglion<sup>14</sup>, abdominal stretch receptor<sup>15</sup> and lateral giant fibre (unpublished work of Roberts). In each case a selective blockage of known inhibitory processes has been found. The effect of picrotoxin on the response of the lateral giant fibre to second root stimulation is shown in the top trace of Fig. 1, *E1*. Earlier parts of the response are little affected, but the gamma component, which ordinarily does not measure more than about 5 mV, is much augmented and spiking occurs at about 15 mV depolarization. It seems reasonable to attribute this augmentation to a release of the system from inhibition.

If the habituation phenomenon seen in the giant fibre is caused by an inhibitory process, then the present disinhibited preparation might be expected to respond more reliably than a normal preparation to repeated stimulation. A comparison of the effects of stimulus repetition in the normal (Fig. 1, *D1* and 2) and picrotoxin poisoned (Fig. 1, *E1* and 2) preparations shows that this is decidedly not the case; the effect, if any, of the picrotoxin is to make the response more labile than normal.

We conclude that there is at least one class of central nervous inhibition which cannot be held responsible for the decrement of the beta component and the consequent habituation of the crayfish lateral giant fibre escape reflex. Spencer, Thompson and Neilson<sup>16</sup> similarly failed to prevent habituation of the flexion reflex in the spinal cat by application of either picrotoxin or strychnine. While there may be some inhibitory processes of the crayfish nervous system which are not attacked by picrotoxin, we feel that the best hypothesis is that habituation of the crayfish escape reflex is caused by a depression intrinsic to the reflex's excitatory pathways. Desensitization of postsynaptic membrane, depletion of transmitter, and depression of electrogenic processes in axonal or dendritic arborizations are salient as potential mechanisms of action.

## Regulation of Noradrenaline Biosynthesis in Nerve Tissue

THE noradrenaline (NA) content of sympathetically innervated organs remains remarkably constant, at a concentration characteristic of each individual organ, during widely varying states of nerve activity<sup>1</sup>. Because an increase in the frequency of nerve impulses is associated with an increased loss of NA from the neurone, its capacity to maintain an essentially unchanged NA content has been regarded as evidence that the synthesis of NA is accelerated by nerve activity<sup>1</sup>. The opposite view—that the synthesis of NA in the neurone proceeds at a constant “supramaximal” rate, independent of activity—has, however, also been proposed<sup>2,3</sup>.

Several recent reports indicate that the synthesis of NA is indeed accelerated when the nerve impulse frequency is increased<sup>4-9</sup>. We have found that the mechanism of this regulation of synthesis does not seem to be related to the depolarization phenomenon itself, or to variations in the activity of the effector organ<sup>9</sup>. Our results show that the factor triggering acceleration of synthesis, or removal of its inhibition, appears rather to be depletion of some critical NA “pool” in the tissue.

This implies that the rate of NA synthesis may be controlled by variations in the NA content of the neurone. This concept is supported by recent *in vitro* evidence. Thus on incubation with different tyrosine hydroxylase preparations Nagatsu, Levitt and Udenfriend<sup>10</sup> found that a DL-NA concentration of  $2 \times 10^{-4}$  moles/l. in the incubation medium caused a 25–50 per cent inhibition of the ring hydroxylation of tyrosine, which is considered to be the rate-limiting step in the formation of NA.

Although the inhibition of the synthesis of NA induced by NA described by these authors was very incomplete and required high concentrations of NA in the medium, we have recently been able to show that the synthesis of NA from tyrosine in a fraction from a homogenate of bovine splenic nerves can be inhibited by as much as 85 per cent by concentrations of noradrenaline as low as  $1.2 \times 10^{-5}$  moles/l. in the medium. We also found that the inhibition operated not only at the first step in the synthesis sequence but also at the last step, the  $\beta$ -hydroxylation of dopamine (Fig. 1).

The tissue used for these experiments was a preparation of bovine splenic nerve granules<sup>11</sup> obtained by ‘Ultra-Turrax’ homogenization of de-sheathed splenic nerves in ice-cold isotonic potassium phosphate, pH 8.2, and subsequent removal of nuclei, mitochondria and coarse tissue fragments by centrifugation at 9,000g for 10 min. The supernatant fraction from this centrifugation, containing the specific NA-storing granules, was passed over a column of aluminium oxide in order to remove non-bound extra-

Fig. 1. The principal biosynthetic pathway leading to the formation of NA from tyrosine. Diagrammatic representation of the two mechanisms for the regulation of the synthesis of NA, described in the text.

Fig. 2. Inhibition of the NA and dopamine formation from tyrosine by addition of NA to the incubation medium. Sections from ion exchange chromatograms of the washed pellet and of the combined wash and supernatant fractions.

granular NA (ref. 12). The effluent was adjusted to pH 7.5, divided into fractions of 8 ml. and incubated in stoppered plastic centrifuge tubes at 20° C for 60 min in the presence of  $3 \times 10^5$  c.p.m./ml. of tyrosine labelled with tritium (New England Nuclear Corp., L-tyrosine-3,5- $^3$ H, specific activity 4 c./mmole).

Non-labelled NA was added to the medium to give final concentrations of from 0 to  $9.6 \times 10^{-5}$  moles/l.

After the incubation period the granule fraction was separated from the medium by centrifugation at 50,000*g* for 30 min. The sediment obtained was washed and re-centrifuged. The formation of NA and of the two intermediates, dihydroxyphenylalanine and dopamine, was determined by cation exchange column chromatographic analysis of extracts of the washed high speed sediment and of the pooled supernatant and wash fractions. Tyrosine was removed from the extracts before chromatography, by passing them at pH 8.4 over a column of aluminium oxide, which selectively retains catechol compounds, while allowing non-catechol material to pass into the effluent and water wash. Catechols were then eluted with perchloric acid, and the eluate analysed by chromatography. The positions of dihydroxyphenylalanine, dopamine and noradrenaline in the chromatograms were determined by reading the spontaneous fluorescence (activation at 285 mμ, fluorescence at 335 mμ) in an Aminco-Bowman spectrophotofluorometer. The radioactivity of the different fractions was determined by counting 0.5 ml. aliquots in a 7:3 toluene-absolute ethanol solution containing 4 g of 2,5-diphenyloxazol and 100 mg of 1,4-bis-2(4-methyl 5-phenyloxazolyl) benzene per litre of toluene, by means of a Packard liquid scintillation spectrometer. (The overall recovery of noradrenaline put through the entire procedure ranged from 70 to 90 per cent.)

The results obtained are presented diagrammatically (Fig. 2) by a series of ion exchange chromatograms from a typical experiment. Radioactive dihydroxyphenylalanine never accumulated to any considerable extent and was thus not included in the figure. About 2.5 per cent of the tyrosine added to the control tube, in which the extragranular medium was essentially free of NA, was converted to catecholamine. About one-third of the

dopamine formed was β-hydroxylated to NA. Because the tyrosine content of these preparations, determined by the fluorimetric method of Waalkes and Udenfriend<sup>13</sup>, was found to range from 0.3 to  $0.5 \times 10^{-5}$  moles/l., the NA formed amounted to 50–70 ng/g splenic nerve/h, corresponding to about 5 per cent of the total endogenous NA content of the granules. In the presence of increasing concentrations of NA in the medium the formation of catechol compounds was inhibited to a progressively increasing extent. The synthesis of dopamine was blocked to a lesser extent than that of NA. In the experiment shown in Fig. 2 the inhibition of dopamine and of NA formation was 57 and 85 per cent, respectively, at a concentration of NA in the medium of  $1.2 \times 10^{-5}$  moles/l., and 77 and 97 per cent at  $4.8 \times 10^{-5}$  moles/l.

Our results confirm and extend the finding of Nagatsu *et al.*<sup>10</sup> that the synthesis of NA from tyrosine can be inhibited by high concentrations of NA in the medium. In agreement with their results, our experiments indicate that the enzyme tyrosine hydroxylase is inhibited by an accumulation of the end-product of the biosynthesis pathway, NA. In the present experiments, however, a much more complete inhibition of the formation of catechol was obtained at much lower concentrations of NA.

Moreover, the block of synthesis of NA in our experiments occurred not only at the first but also at the last step in NA biosynthesis. According to previous results in this laboratory, the β-hydroxylation of dopamine appears to be the only step in NA synthesis requiring the presence of granules. The concept that dopamine is formed from tyrosine extragranularly is supported by the observation in the present experiments that more than half the NA formed was found in the washed high speed sediment, while less than 2 per cent of the dopamine formed was granule-bound. This finding also suggests that drugs known to antagonize the uptake and retention of amines in the nerve granules<sup>10</sup> interfere with the synthesis of NA exclusively by blocking the conversion of dopamine to NA (ref. 11), while not affecting the formation of dopamine from tyrosine. This implies that dopamine must become granule-bound before it can be β-hydroxylated<sup>12</sup>. Because NA in the medium competitively inhibits the uptake and retention of dopamine in the granules<sup>12</sup>, the block of synthesis at the dopamine β-hydroxylation step caused by NA in the medium is most likely to result from competitive inhibition of the uptake of dopamine into β-hydroxylation sites.

These *in vitro* results show the feasibility of control of the synthesis of NA by changes in the concentration of this product outside the granules. Thus the test-tube results obtained with subcellular fractions strongly support the conclusions proposed on the basis of experiments with intact tissues that depletion or accumulation of NA in strategic parts of the neurone are the factors which trigger the homeostatic adjustment of the rate of synthesis of NA, which results in the maintenance of a constant transmitter level in the neurone. Our results have established that control of NA synthesis can be exerted at the first step of the biosynthetic pathway. This finding provides an example of regulation of the synthesis of a neurotransmitter by the classical principle of feed-back control of the rate-limiting step of the biosynthetic pathway, by variations in the accumulation of the end-product.

We also found, however, that control of synthesis can be exerted by a different mechanism, operating at the DA β-hydroxylation step. Observations in this laboratory suggest that under normal conditions regulation of synthesis occurs primarily by the first mechanism (that is, by variation in the degree of inhibition of the tyrosine hydroxylation step). It is conceivable, however, that in special circumstances, such as after treatment with drugs like reserpine, the synthesis of NA may also be affected by interference with the transport and/or binding of

dopamine<sup>1,16</sup>, formed extragranularly to the dopamine hydroxylating sites in the granules.

This investigation was supported by a US Public Health Service postdoctoral fellowship from the National Institute of General Medical Sciences, and by a grant from the Swedish Medical Research Council.

## RADIOBIOLOGY

### Haematopoietic Repopulation after Intestinal Shielding from X-irradiation

THE two methods most commonly used to produce repopulation after irradiation are: (1) exogenous colonization, or "grafting", by the injection of healthy haematopoietic tissue into a heavily irradiated recipient<sup>1-3</sup>; (2) endogenous colonization accomplished by the shielding of haematopoietic tissue<sup>4,5</sup>. In comparing these two techniques, Porteous and Lajtha<sup>6</sup> concluded that, after radiation, exocolonization—involving considerable cellular handling—gives a different pattern of recovery from that observed with endocolonization.

Whereas grafted lymph node and foetal thymus suspensions<sup>7</sup> and thoracic duct lymphocytes<sup>8</sup> have failed to elicit "post-irradiation" recovery, Jacobson *et al.*<sup>9</sup> demonstrated that 26.6 per cent of the mice, the exteriorized gut of which was shielded from 1,025 r., survived for 30 days and their haematopoietic recovery was nearly complete in 8 days. The present experiments were performed in an attempt to resolve this apparent discrepancy and they consisted of examining the haematopoietic potential of the shielded intestine in the irradiated mouse.

CF-1 virgin female mice were anaesthetized with an intraperitoneal injection of 'Diabital' (1.8 mg/0.5 ml. sterile saline/mouse) and randomly divided into four groups: (1) about 75 per cent of the intestine and mesentery was exteriorized and shielded with lead while the rest of the body was being irradiated; (2) a similarly treated group received whole-body irradiation while the gut and mesentery was exteriorized but not shielded; (3) whole-body irradiation of intact animals; and (4) a normal, non-irradiated control group. The irradiation was carried out using a 250 kVp. 'Maximar' unit operating at 15 m.amp with a half-value thickness of 2 mm copper at

a source to mid-line distance of 45 cm. Each irradiated animal received 700 r. at 60 r./min and when shielding was used the thickness of the lead was sufficient to attenuate the dose to less than half of 1 per cent.

Six days after irradiation, all animals were injected with 0.5 µc. of iron-59 (specific activity: 15.5 mc./mg iron) as ferrie chloride in 0.2 ml. of buffered solution, by way of their tail vein. Forty-eight hours later (that is, a total of 8 days after irradiation) all animals were bled and their peripheral erythrocyte and whole spleen radioactivities were determined in a well-type scintillation counter. Macroscopic splenic colonies were counted and then routinely sectioned and stained for histological examination.

Fig. 1. Effects of 700 r. X-irradiation and gut shielding on splenic colonization and erythropoiesis as indexed by erythrocytic and splenic incorporation of iron-59. The number of animals in each group is enclosed in brackets.

The results are summarized in Fig. 1. Animals which had their intestines shielded during irradiation showed higher incorporation of iron-59 into peripheral red blood cells and spleens than those groups of animals which received whole-body irradiation while their gut was either exteriorized or intact and not shielded ( $P < 0.0005$ ). The number of splenic colonies in group 1 animals was greater than that of the control groups. Histological examination of serially sectioned spleens from group 1 mice revealed intensive areas of haematopoiesis with numerous mitotic figures. Erythrocytic, myelocytic and megakaryocytic foci were observed as individual colonies, as well as intermixed. In addition to these, aggregates of lymphocyte-like cells were noted. Spleens from animals in groups 2 and 3 did not contain any observable haematopoietic foci.

The most likely origins of the repopulating cells in the shielded region are the mesenteric lymph nodes and Peyer's patches, although the possibility cannot be precluded that migratable stem cells also exist in the non-lymphoid tissue or blood of the protected area. Failure of these cells to show colonizing capacity on transplantation may be the result of their sensitivity to handling, whereas similar cells *in vivo* may retain this property. The findings in this experiment of increased erythropoiesis and colonization in the group of animals of which the gut was shielded probably result from the seeding of such cells into the spleen and bone marrow.

We thank Mrs Kathleen Porteous and Miss Marion G. Oakes for their technical assistance in this work, which

was supported by grants from the National Heart Institute of the US Public Health Service.

## PATHOLOGY

### Nuclear Pockets in Normal Leucocytes

RECENTLY there have been several reports on nuclear blebs found in human leukaemic cells<sup>1</sup> and in human bone marrow cells of leukaemic patients on drug therapy<sup>2</sup>. Similar nuclear structures have also been found in developing human<sup>3</sup> and guinea-pig<sup>4</sup> thymocytes, and possibly in Burkitt's lymphoma<sup>5</sup>. Anderson<sup>6</sup> noted identical nuclear structures in myeloblasts from patients with treated and untreated acute myelocytic leukaemia and referred to them as nuclear loops.

Fig. 1. Nuclear pockets in nucleus of lymphocyte ( $\times 15,750$ ).

Electron microscopy of leucocytes from eight normal people showed that nuclear blebs, which we prefer to term "nuclear pockets" (see Fig. 1), were present in the lymphocytes and neutrophils of all eight. We consider the term "nuclear pockets" to be more accurate than "nuclear blebs" as we have demonstrated by serial sectioning. The significance of nuclear pockets in leukaemia

cells has to be evaluated in relation to frequency and ease of demonstration in leucocytes from normal people.

### Formation of Methanol by an Enzyme in an Ectopic Pinealoma

THE tissue of origin of a tumour is conventionally determined by histological examination. It has been possible to identify some tumours by their secretion of substances specific to tissue into the general circulation. Thus pheochromocytomata—tumours which originate in chromaffin tissue—secrete large amounts of catecholamines, hormones normally manufactured by chromaffin tissue. Malignant carcinoids, derived from the enterochromaffin cells of the intestine, may secrete serotonin, a normal product of enterochromaffin cells. Pheochromocytomata and malignant carcinoids respectively contain high concentrations of catecholamines and serotonin. These tumours presumably also contain the enzymes required to synthesize these compounds. Similar unique biochemical characteristics have not yet been described for tumours within the central nervous system. Recent studies from this laboratory have identified at least two enzymes which are highly localized in specific sites in the central nervous system. It was found that hydroxyindole-*O*-methyl transferase (HIOMT), the enzyme which *O*-methylates *N*-acetylserotonin to form melatonin<sup>1</sup>, is present almost exclusively in the pineal gland of several mammalian species<sup>2</sup>. HIOMT activity has been found to be of comparable magnitude in the pineal glands of human beings from 3 to 70 years of age, suggesting that calcification of the human pineal gland during adulthood does not interfere with this biochemical function<sup>3</sup>. Melatonin, the product of the enzyme action, has been found to exert an inhibitory influence on gonadal growth and on the oestrous cycle in rats<sup>4</sup>. Wurtman *et al.*<sup>5</sup> have identified melatonin and HIOMT activity in a metastatic parenchymatous pinealoma and suggested the utility of this enzymatic assay in the diagnosis of this tumour.

Axelrod and Daly<sup>6</sup> have described an enzyme which forms methanol and is localized in the pituitary gland of several mammalian species including man. The reaction involves either the methylation of water by *S*-adenosylmethionine to form methanol or a hydrolytic cleavage of *S*-adenosylmethionine to form methanol and *S*-adenosylhomocysteine as follows:

The methanol forming enzyme in the anterior pituitary has one-fourth the activity of the posterior pituitary, and negligible activity is present in all other tissues examined, including brain, pineal gland, liver, lung, kidney and adrenal.

The present report will describe biochemical investigations of an ectopic pinealoma. Ectopic pinealomata are frequently located in the region of the optic chiasma. Although the histology of these tumours resembles that of pineal parenchymal tissue, their tissue of origin is not well established. It is thought that such tumours can arise in the pineal gland and metastasize to the floor of the third ventricle and the optic chiasma. They may also originate in the

Table 1. METHANOL-FORMING ACTIVITY IN PINEALOMA AND NORMAL TISSUES

Tissue	Labelled methanol formed (mμmoles/g/h)
Ectopic pinealoma	70
Whole human pituitary	18*
Bovine pituitary	
Posterior	77*
Anterior	25*

\* These values were obtained in previous experiments<sup>4</sup>.

Soluble supernatant fractions obtained from 17 mg of the tumour were incubated with 10 mμc. of <sup>14</sup>C-S-adenosylmethionine (40 mμc./mole) and the mixture was assayed for formation of <sup>14</sup>C-methanol as described earlier<sup>4</sup>.

third ventricle, the pineal gland being intact, or they may arise directly from the chiasmal region. It has been suggested that these tumours arise from misplaced primordial germ cells and should be considered germinomata<sup>7</sup>. In the present investigation the activities of enzymes which are specific to the pineal or pituitary glands in an ectopic pinealoma have been measured to ascertain the tissue of origin of this tumour.

Tissue was obtained from a spinal cord metastasis of an ectopic pinealoma which had been removed at craniotomy from the region of the third ventricle of a patient who had the symptoms of a left temporal haemianopsia and diabetes insipidus. Histologically the tumour resembled a germinoma and was very similar to that described by Wurtman *et al.*<sup>5</sup>.

The tumour from the spinal area was first examined for HIOMT (melatonin forming activity) by a sensitive assay which can detect the formation by an enzyme of as little as 1 μmole of melatonin<sup>8</sup>. The tumour was found to be devoid of HIOMT activity. In marked contrast, a metastatic parenchymatous pinealoma<sup>9</sup> and normal human pineal tissue<sup>3</sup> have considerable HIOMT activity. Moreover, Wurtman and Kammer<sup>9</sup> detected HIOMT activity in an ectopic pinealoma. These results would suggest that the tumour was not derived from functional pineal parenchymal tissue.

To examine the possibility that the tumour might be of pituitary origin, it was assayed for methanol forming enzyme activity, which has been found to be localized to the pituitary gland, by a method previously described<sup>6</sup>. The tumour formed 70 mμmoles methanol/g tissue/h (Table 1). This amount was more than that formed by human pituitary gland.

These observations indicate that the biochemistry of this tumour resembles that of pituitary gland tissue and might therefore be of pituitary origin. The especially high activity suggests that it might originate from the posterior pituitary gland which has the highest capacity to form methanol in the pituitary.

Another enzyme activity which is highly concentrated in normal pituitary gland tissue is the histamine methylating enzyme, histamine-methyl-transferase. The highest histamine-methyl-transferase activity of all parts of the central nervous system and all peripheral organs examined has been found in the posterior pituitary gland<sup>10</sup>. Although posterior pituitary has the highest histamine-methyl-transferase activity, this enzyme is present in other tissues<sup>11</sup>. The ectopic pinealoma was assayed for histamine-methyl-transferase activity by a method described earlier<sup>12</sup>. The tumour was capable of synthesizing at least 2.34 μmoles of methylhistamine/h/g tissue. This amount of histamine-methyl-transferase activity is greater than that demonstrated previously for any other tissue except for the posterior pituitary gland of the monkey<sup>2</sup>. The high histamine-methyl-transferase activity of the tumour is consistent with an origin in the pituitary gland. The mammalian pineal gland, however, also has fairly high concentrations of this enzyme<sup>2</sup>.

The ectopic pinealoma has been thought to represent a germinoma<sup>7</sup> or teratoma<sup>13</sup>; both these sometimes contain high concentrations of gonadotropins. Accordingly, the ectopic pinealoma was assayed for gonadotropin content (by Dr Roy Hertz). The tumour was found to be devoid of gonadotropin activity as measured by the mouse

uterus weight method<sup>10</sup>. This method can detect as little as 0.1 units of gonadotropin activity.

The presence of the pituitary specific methanol forming enzyme in the ectopic pinealoma and the absence of the pineal specific melatonin forming enzyme, HIOMT, indicate that the tumour came from the pituitary rather than the pineal. The tumour appeared, at operation, to originate near the pituitary stalk. Because the specimen examined for enzyme activity was metastatic to the spinal cord, it is unlikely that contamination from pituitary gland tissue provided the methanol forming enzyme activity. Wurtman and Kammer<sup>9</sup> have independently examined an ectopic pinealoma which contained considerable HIOMT activity and had little or no methanol forming capacity. Histologically, the ectopic pinealoma investigated by Wurtman and Kammer<sup>9</sup> closely resembled the tumour examined here. The markedly different enzyme characteristics of these two tumours would indicate that they constitute separate and distinct pathological entities.

The histological appearance of a tumour is frequently not sufficiently distinctive to indicate its pathological derivation. The ectopic pinealoma is an example. Histologically it resembles seminomata of the testis, dysgerminomata of the ovary, teratomata, and a variety of mediastinal tumours. The results of the present study and the results of Wurtman and Kammer<sup>9</sup> suggest that there are two different biochemical classes of ectopic pinealomata.

Histological examination is sometimes unable to predict fully the malignant potential of certain tumours. It is possible that enzyme characterization of tumours might aid in revealing the pathological derivation of tumours and might be useful in assessing their malignant potential.

## CYTOLOGY

### Longitudinal Differentiation of the Small Intestine

THE inner surface of the small intestine is covered by a "monolayer" consisting of simple epithelium and a smaller number of goblet cells. The epithelial cells differ in the various parts of the small intestine. Their vertical differentiation was suspected<sup>1</sup> and confirmed by Dahlquist

and Nordström<sup>2</sup>. This differentiation arises from the fact that in the crypts of Lieberkühn the cells can undergo mitosis, but are incapable of digesting and absorbing nutrients. According to Grobstein's terminology<sup>3</sup>, this state corresponds to covert differentiation. Towards the apex of the intestinal villi, the cells gradually develop the enzyme pattern necessary for digestion and absorption, but lose their ability to undergo mitosis. This state would, according to Grobstein, correspond to overt differentiation.

A longitudinal differentiation of small intestinal epithelium has also been demonstrated in morphological and functional respects. Nutrients enter the small intestine from an oral direction. In general, the capacity of the intestinal epithelium to absorb (transport) important foodstuffs (glucose, sodium ions, water, fats) tends to decrease in the aboral direction, that is, towards the lower part of the intestine<sup>4</sup>. The activity of certain enzymes<sup>5,6</sup> and cell turnover<sup>7</sup> show a similar longitudinal distribution in the intestine.

Much less frequently the lower (aboral) part of the small intestine displays either greater or exclusive capacity to absorb a given nutrient. Good examples are the lactose or carbohydrate-dependent absorption of calcium<sup>8</sup>, the absorption of conjugated bile acids<sup>9,10</sup> and of the  $B_{12}$ -intrinsic factor complex. The last capacity has been

Fig. 1. Duodenum of suckling rat. Paraffin embedding, with haematoxylin and eosin stain. The epithelial cells resemble those of adult animals.

Fig. 2. Ileum of suckling rat. Paraffin embedding, with haematoxylin and eosin stain. The epithelium consists of "hollow" cells. In the apical region of the villi inclusion bodies are apparent in the vacuoles.

Fig. 3. Unfixed and unstained cell suspension from ileum of suckling rat. The cell at the bottom is swollen. The vacuole (V) and the brush border (B) are clearly visible on each cell. The nucleus (N) is ghost-like.

Fig. 4. Ileum of suckling rat. Paraffin embedding, with periodic acid-Schiff reaction. "Hollow" cells with inclusion bodies are apparent.

demonstrated in the ileum of man, dog, guinea-pig, golden hamster and in the jejunum of the rat<sup>11</sup>.

We became interested in morphological differences between the upper and lower parts of the small intestine through a histological study of the absorption of gamma-globulin. The duodenal epithelial cells of suckling rats (Fig. 1) were found to resemble those of adults, whereas their ileal cells were of a different type, showing large vacuoles giving the impression of being "hollow" in paraffin-embedded sections (Fig. 2). These vacuoles were also clearly visible in the unstained suspension of living cells (Fig. 3) and contained fluid but no fat or mucus. On staining with mucicarmine, only a few goblet cells were seen among the "hollow" cells. The vacuoles of the latter frequently contained periodic acid-Schiff-positive inclusion bodies, yellow in colour in unstained and eosinophilic in stained preparations (Fig. 4). The relationship of these bodies to gamma-globulin absorption will be described in detail in another paper. Transition between the "hollow" and normal epithelial cell was gradual. Both cell types, as well as their transitory forms, have been recognized by us on electron micrographs by Clark<sup>12</sup> and Kraehenbuhl *et al.*<sup>13</sup>. These authors, however, have not distinguished between the large vacuole as a marker of a special cell type and the small

Fig. 5. Ileum of newborn guinea-pig. Paraffin embedding, with haematoxylin and eosin stain. The epithelium consists of "hollow" cells, but no inclusions are apparent.

ones as that of a physiological condition, the absorption of gamma-globulin.

Macroscopically the upper part of the small intestine of the suckling rat is milky white, whereas its lower part, where the "hollow" cells are located, is yellowish brown in colour. The inclusion bodies are probably responsible for this coloration. This part of the suckling rat's intestine stains slightly with orally administered vital stains<sup>14</sup>.

The ileal cell type described is not specific for the suckling rat. We have found it also in mouse and guinea-pig, but failed to detect it in dog, cat, goat and pig. Unlike the rat, guinea-pigs had no inclusion bodies in their "hollow" cells (Fig. 5).

The parenchymal cells of different organs usually differ in morphology, function and localization. In view of this fact the small intestine of the suckling rat can be visualized as two tube-like organs in sequence, incompletely separated from each other by the transitional cellular region. This model is not so well defined for adult mammals as for the suckling rat, and is confined to functional characteristics in the former case.

These observations suggest a new aspect which should be taken into account when describing the characteristics of the epithelial lining of the small intestine.

## Mast Cells free of Histamine in *Rana catesbiana*

THE theory that mast cells are the source of histamine is based exclusively on investigations carried out on mammals and it is not known whether it also holds true in non-mammalian vertebrates. It is not even known whether histamine is contained in the tissues of these animals.

In the course of a study of the mast cells in the tongue of the bullfrog, *Rana catesbiana*<sup>1</sup>, it was noted that intracardial or local injections of a large dose of the histamine releaser compound 48/80 did not cause any distinct morphological changes in the mast cells nor did it bring about a general shock reaction. Although Arvy<sup>2,3</sup> has reported that frog mast cells are sensitive to the histamine releaser, stilbamidine, careful reading of his reports reveals that he found cytological changes in the mast cells only in the vicinity of the local injections. Another experiment which we have carried out has also shown that a large dose of histamine administered intracardially provokes no detectable general change in the bullfrog. These observations caused us to doubt the relation between histamine and mast cells and also to doubt the biological significance of histamine in this animal.

In a histological survey of sections and spreads of various organs (fixed in 10 per cent formalin containing 4 per cent basic lead acetate and stained in acidic toluidine blue), it was found that the tongue, the mesenteries and liver are suitable material for an analysis of the relationship between the histamine value and the mast cell population. The chief reason for this is that the tongue and the mesenteries are very rich in mast cells, whereas the liver is almost completely free of them. Histamine was extracted according to the method of Code<sup>4</sup> and assayed by the contraction of guinea-pig ileum in a Tyrode bath containing atropine. Neocatergan was used to confirm that the effective substance was histamine.

The concentrations of histamine in the various organs obtained from five bullfrogs of both sexes, weighing 250–600 g, are given in Table 1. For comparison, we include values for histamine in the abdominal skin and mesenteries assayed in 4 male (140–170 g) rats of the Wistar strain. The table shows that in striking contrast to those of the rat, the tissues of the bullfrog contain only a trace of histamine. This becomes more evident if one compares the concentrations in the mesenteries of the two animals. The concentration of histamine in the mesenteries of the bullfrog is as little as 1/130th of that in the rat, although the distribution of mast cells in the former is about four times as great as in the latter. Taking into account the fact that the mast cells of the frog are smaller in size, the total volume of mast cells contained within one unit of frog mesentery is at least equal to that contained within the same quantity of rat mesentery.

The liver of the bullfrog, which was, as found by Arvy<sup>3</sup> in *Rana esculenta*, lacking in mast cells, showed concentrations of histamine not essentially different from those in the organs rich in mast cells. This suggests that in the bullfrog histamine is not carried by mast cells as in the mammals. This is supported also by histochemical observations. Fluorescent *o*-phthalaldehyde stain for histamine<sup>5</sup> was applied to the spreads of the mesenteries and tongue of the bullfrog. Although a bright yellow fluorescence was detected in the mast cell cytoplasm in the rat mesenteries examined as a control, it could not be found in the mast cells of the bullfrog.

The possibility that the mast cells of the bullfrog carry serotonin—another biogenic amine known to be contained in the mast cells of the rat and mouse—instead of histamine was rejected by histochemical examination. Fluorescence microscopy of the spreads of bullfrog tongue and mesenteries exposed to paraformaldehyde vapour<sup>6</sup> revealed that the mast cells did not fluoresce; Padawer<sup>7</sup> has recently reported similar findings with *Rana temporaria*.

Table 1

		Histamine value ( $\mu\text{g/g}$ wet tissue)	Mast cell count
Bullfrog	Mesentery	0.19 $\pm$ 0.06	+++
	Tongue	0.04 $\pm$ 0.01	+++
	Liver	0.07 $\pm$ 0.01	—
Rat	Mesentery	24.8 $\pm$ 4.4	++
	Abdominal skin	29.8 $\pm$ 3.1	++

Preliminary results obtained in the course of a comparative study of various animals in our laboratory suggest that mast cells are free of histamine throughout the teleosts and amphibia and that it is not present below the level of the reptilia.

## GENETICS

### Haptoglobins, Transferrins and Serum Gamma-globulin Types in Malayan Aborigines

THE Malayan aborigines form a distinct ethnic group which is socially and anthropologically different from the three main population groups in Malaya—the Malays, the Chinese and the Indians. The aborigines live mostly in the jungle, follow their own customs and beliefs and have little contact with non-aborigines. They are plagued by diseases, the most common of which are malaria and tuberculosis. Genetically the aborigines are of particular interest. Studies have revealed high frequencies in this population of certain haematological abnormalities: haemoglobin E ranges from 8 to 50 per cent in different groups<sup>1</sup>, glucose-6-phosphate (G-6-P) dehydrogenase deficiency from 8 to 23 per cent<sup>1</sup>, and hereditary ovalocytosis is found in 12.3 per cent of aborigines examined<sup>2</sup>. These high frequencies may be due to malaria or inbreeding or both. We now report the results of a preliminary study of haptoglobins, transferrins and serum gamma-globulin types in Malayan aborigines.

Blood samples obtained from various aborigine groups were frozen and shipped by air to San Francisco. Haptoglobin types were determined by starch-gel electrophoresis by the method of Smithies<sup>3</sup>. A highly sensitive benzidine solution was used to stain the haemoglobin-haptoglobin complex. In those instances when haptoglobin was not detected, the serum sample was run three times before ahaptoglobinaemia was diagnosed. Transferrin types were determined from the same starch gel by the autoradiographic method of Giblett *et al.*<sup>4</sup>, in which they are identified by the use of radioactive iron-59. At a later stage a method of micropurification, followed by electrophoresis, was also employed<sup>5</sup>. Typing for hereditary gamma-globulin (Gm) groups was performed by the inhibition of agglutination reactions using standard tube systems described by Fudenberg and Kunkel<sup>6</sup>.

Blood from 266 Malayan aborigines, 72 jungle fighters and 194 villagers and aboriginal hospital personnel was examined for haptoglobins. The aborigines were from different jungle areas, and 64 villagers had to be excluded from the study because they were related to persons included. Type 1-1 was found in six aborigines, 2-1 in

79, and 2-2 in 101, and haptoglobin was not detectable in sixteen. The gene frequencies for Hp<sup>1</sup> and Hp<sup>2</sup> were respectively 0.24 and 0.76. The frequency for haemoglobin E in the whole group was 34.0 per cent, for G-6-P dehydrogenase deficiency, 15.7 per cent, and for ovalocytosis, 12.0 per cent. Of the sixteen haptoglobin-negative persons, six carried haemoglobin E and ten did not; two were deficient in G-6-P dehydrogenase and fourteen had normal amounts in the erythrocytes; two had ovalocytosis and fourteen had not; one had malarial parasites and fifteen were uninfected at the time of study. From these data, malaria, haemoglobin E and G-6-P dehydrogenase deficiency did not seem to be the cause of the high frequency of haptoglobin-negative persons in this population group.

The same serum samples were also studied for transferrins. Among 202 sera from unrelated subjects, 196 contained only Tf C and six contained Tf CD. The Tf D resembled Tf D<sub>Chi</sub> and Tf D<sub>1</sub>. The exact identity of the Tf D is being studied at the Department of Zoology, University of Texas, Austin. The Tf D<sub>Chi</sub> has been found to differ in amino-acid substitution from that of Tf D<sub>1</sub> (ref. 7).

The attention of population geneticists has recently been attracted to the examination of hereditary gamma-globulins. The Gm types, because of their typical Mendelian inheritance, have proved useful in both anthropological and genetic studies, and the frequencies of different phenotypes vary greatly from one population to another. The systems for the detection of hereditary Gm types have steadily increased in number and, like the blood group system, they have become more and more complex. We examined various Gm factors in the sera from Malayan aborigines, and results were as follows: results of tests for Gm (a) and (b) on 147 sera from unrelated persons were 99 per cent positive; of 72 tested for Gm f, 97 per cent were positive. Gm x was uniformly negative in 107 sera from unrelated persons, and negative results were also uniformly obtained for Gm-like (Gm-c) activity in 131 sera. This pattern differs from the patterns found in Caucasians, Negroes, Australian aborigines, Japanese and Chinese.

We thank Dr H. E. Sutton for providing a standard Tf CD<sub>Chi</sub> and Dr E. R. Giblett for standard samples containing Tf B<sub>2</sub>C and Tf CD<sub>1</sub>.

This work was supported by a research grant, and by the University of California International Center for Medical Research and Training with a research grant from the Office of International Research, both from the National Institutes of Health, US Public Health Service, and by a grant from the University of California School of Medicine Committee on Research.

*Note added in proof.* Since completion of this manuscript, Dr. H. E. Sutton of the Department of Zoology, University of Texas, has reported that our Tf D is Tf D<sub>Chi</sub>. We are grateful for his help.

## BIOLOGY

## Population Growth and Blood Groups

THE population explosion throughout the world is an important problem for governments and a topic much debated among demographers and economists. Any hint about the natural factors which might exercise control over population growth would seem to be worthy of further investigation by experts. The ranges of fertility in different communities vary and the variation would seem to be heritable. Mourant<sup>1</sup> states that "blood group studies are probably at present more valuable as a source of genetical information about human populations than studies of all other factors combined, and blood groups will surely remain for many years more important than any other class of factors".

Sperm counts in millions/ml.	Table 1 Blood groups				Total
	O	A	B	AB	
> 40	57 48%	50 41%	10 8.3%	3 2.5%	120
20-40	13 53%	9 37.5%	2 8.3%	0	24
0-20	10 35.7%	14 50%	3 10.7%	1 3.6%	28
Nil	15 37.5%	19 47.5%	6 15%	0	40
Blood group (donors) distribution this area	50.7%	36.0%	10.8%	3.0%	212

As part of our clinical study of male infertility we record the blood groups of the patients. The results in 212 such subjects are set out in Table 1. The most striking feature is the relative increase of group A and the relative decrease of group O among the azoospermic and oligospermic men. (We use the term azoospermic to mean complete absence of sperms in the samples of semen examined.) Preliminary statistical examination of these data on the basis of the standard error of the difference when compared with the normal distribution for this area of Scotland (shown in the lowest line of Table 1) suggests that the excess of group A is just at the level of significance. The proportion of A and O in our series of patients has not changed appreciably in the present group of 212 compared with our analysis of the first 116 some time ago. In view of this observation, we wonder whether there is any correlation between the frequency of blood group A in a community and its rate of population growth. A superficial examination suggests that there is. For example, in India, which has a rapid growth of population, the frequency of blood group A is of the order of 25 per cent, whereas in Europe with a lower rate of population growth the frequency of blood group A is of the order of 40 per cent.

Perhaps an expert in population studies would like to comment on or pursue this point.

## Westerly Extent of the Range of Three African Lorisoid Primates

IN 1958 Booth<sup>1</sup> reviewed the zoogeography of West African primates and followed Rosevear<sup>2</sup> in placing the Cross River as the western boundary to the range of three Central African lorisoids. These were the angwantibo, *Arctocebus calabarensis* (Smith), Allen's bushbaby, *Galago alleni* Waterhouse, and the needle-clawed bushbaby, *Euoticus elegantulus* (Le Conte). Schwarz<sup>3,4</sup> and Hill<sup>5</sup> had previously speculated on the Niger as the western

Fig. 1. boundary, but Rosevear's knowledge of this particular area has given much weight to the theory of the Cross River as a faunal barrier. Apparently unknown to Booth, however, angwantibos had been recorded before 1958 (refs. 6 and 7) from Owerri, Umuahia and Aba, which lie far to the west of the Cross River, and Rosevear himself<sup>8</sup> had recorded the animal in a collection brought to him from the Mamu Forest Reserve (see Fig. 1). Through field work in Eastern Nigeria\* we have been able to produce new and positive evidence on the distribution of the angwantibo and the bushbabies.

During the course of many night walks with head-torches in Mamu Reserve we have seen eleven angwantibos, two of which were captured and examined. Angwantibos were recorded in field excursions to two other key points, Akpaka Forest Reserve on the left bank of the Niger near Onitsha (6° 11' N.; 6° 47' E.) and Elele, further south (5° 6' N.; 6° 48' E.). During three nights in Akpaka Reserve nine individuals were seen, one being captured and examined, and at Elele, close to the most easterly distributaries of the Niger Delta, six angwantibos were seen, two of which were captured and examined.

Nsukka, where the university is situated, has a northerly position (6° 51' N.; 7° 24' E.) well inside the Guinea Savannah Zone. Here, during the past 8 months, twenty-four live angwantibos have been brought to the zoo by local natives. In a single expedition further north, to the village of Akpacha (7° 41' N.; 7° 34' E.) in the Igala Division of Northern Nigeria, we made a certain identification of one angwantibo in secondary woodland near the village. This is the most northerly record for the species, and because it is only 23 miles south of the River Benue it seems probable that this large tributary of the Niger forms the northern boundary of the angwantibo's range.

Our records also indicate how abundant the angwantibo is, at least in Eastern Nigeria. The reputation it has of being "very rare"<sup>9-11</sup> is apparently based largely on the accounts of two expeditions to the Cameroons<sup>12,13</sup>, and certainly is not upheld in our area.

\* Note: On May 30, 1967, the former Eastern Region of Nigeria proclaimed itself the Republic of Biafra.

The range of both *Euticus elegantulus* and *Galago alleni* has been found to extend as far west as that of the angwantibo. Specimens of both these animals were already known<sup>2</sup> from within the Cross encirclement, but there were apparently no records from the region between the Niger and the Cross. We have frequently seen *Euticus* in the Mamu Reserve, and have collected two specimens there. It is also common at Elele, where one specimen has been collected. Two Allen's bushbabies were also seen at Elele, and one of these was collected. As yet, we have no evidence to show that these two species of bushbaby range as far north as the angwantibo, and they are probably restricted to the high forest zone.

These observations were made during the course of field work supported by the Wellcome Trust.

### Feeding Behaviour of the Larval Rat Flea *Nosopsyllus fasciatus* Bosc

DURING investigations on the possibility of inter-vector transmission of the rat trypanosome, *Trypanosoma lewisi* Kent, by the rat flea *Nosopsyllus fasciatus* Bosc, new observations have been made on the feeding mechanism and behaviour of the larva.

Flea larvae are claimed to feed on debris<sup>1</sup>. The mandibles are, according to Sharif<sup>2</sup>, used for rasping and scrubbing the food and then pushing it into the mouth. It is well known that blood, which is passed through the body of the adult flea, is an important and in some cases essential factor for the nutritional requirements of the larvae<sup>1</sup>. One species of flea is said to live in the fur of the Arctic hare, in both the larval and adult stages<sup>3</sup>, and there are occasional records of larvae being found on the bodies of their hosts<sup>4</sup>.

The rat flea has been reared in the laboratory after the method of Leeson<sup>5</sup>. It has been observed that the activity of the larvae in the nest debris frequently brings them into close proximity with adult fleas also present in the debris. Such larvae display a definite response to adults of both sexes and will actively pursue and attempt to seize the adults. If an adult flea is stationary among the debris the larva will attach itself by the mandibles, usually to the posterior end, particularly in the pygidial region. The exact point of attachment does not seem to be important provided that it brings the larva close to the anal opening. When the adult defecates the larva releases the grip with the mandibles and imbibes the faecal blood passed out by the adult flea. The blood is rapidly ingested by the larva with a definite sucking action. The speed with which defecation may occur after the attachment of the larva to the adult flea suggests that possibly its presence stimulates defecation. It is

surprising that sucking by flea larvae has not previously been noted, because the musculature of the pharynx suggests that this method of feeding is usual. Rapid sucking of fresh blood, water and rat urine has been observed under experimental conditions.

Flea larvae collected in nests, especially bird nests, are often recorded as having bright red blood in the gut. This suggests that species other than *N. fasciatus* also obtain blood directly from the anus of adult fleas rather than from the droppings which fall in the nest and rapidly dry.

It has also been found that injured adult *N. fasciatus*, especially if the cuticle is punctured, will be attacked and killed by the larvae, and the body contents eaten. There are apparently only two records in the literature of flea cannibalism<sup>6,7</sup>, but observations suggest this must be a fairly common occurrence. It has also been shown experimentally that larval fleas are attracted to injured mites and ticks which they attack and consume.

It would seem therefore that current views regarding the biology of larval fleas require some modification. The mandibles serve in certain circumstances as organs of temporary attachment and the feeding behaviour involves the sucking of fluids and ingestion of semi-liquid blood at the moment of adult defecation. Furthermore, larval fleas are semi-predatory, readily attacking and killing any slightly injured fleas, mites, ticks and other arthropods present in the nest. In view of these observations it is not surprising to find that flea larvae ingest living trypanosomes with blood from the adult, and experiments have shown that the trypanosomes survive up to 14 h in the gut of the flea larva, and in cultures of fleas that are fed on rats infected with *T. lewisi* up to 18 per cent of the larvae examined from these cultures have trypanosomes present in their gut. Such infections are of a transitory nature and apparently they do not play a part in inter-vector transmission. The intimate relationship between larva and adult flea, however, indicates a method by which bacterial or viral organisms infesting the adult flea either on the surface of the body, as in the case of the myxoma virus<sup>8</sup>, or present in the internal organs could be transmitted to the larvae.

I thank Dr P. Tate and the Hon. Miriam Rothschild for constant advice and encouragement and Dr F. G. A. M. Smit for his help in searching for references. The financial support of the Agricultural Research Council is gratefully acknowledged.

### Influence of pH on the Uptake of Phosphate by Barley Plants in Sterile and Non-sterile Conditions

I HAVE shown<sup>1,2</sup> that the uptake of phosphate by intact barley plants, particularly from solutions of low concentration, is greatly influenced by the presence of micro-organisms on and around the roots. The complete exclusion of micro-organisms reduces the quantity of phosphate incorporated into nucleic acids and other com-

Fig. 1. Effect of pH on the uptake of oxygen by micro-organisms cultured from the roots of barley plants and resuspended in 1.0 per cent glucose.

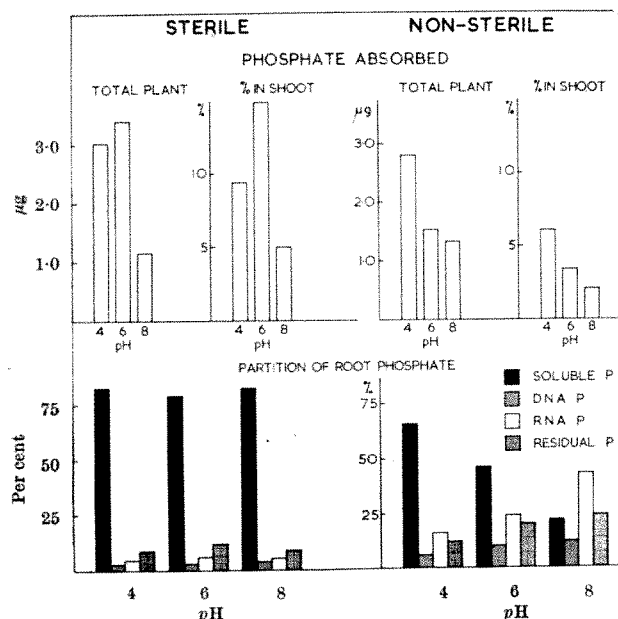

Fig. 2. Effect of pH on the uptake and distribution of phosphate in young barley plants supplied for 3 h with solutions of potassium phosphate under sterile and non-sterile conditions.

plex organic compounds in the root and causes a much greater transfer to the shoot. Similar effects of micro-organisms on the incorporation of phosphate have been shown by other workers<sup>3,4</sup> although the distribution of phosphate within the plants may vary depending on the conditions of the experiments<sup>5</sup>.

The extent to which this influence of micro-organisms varies with pH is here considered. The question is of particular interest in relation to the absorption of phosphate because of the effect of pH on the ionic species which is in solution; whereas at pH 4, 99 per cent is present as  $H_2PO_4^-$ , only about 13 per cent is in this form at pH 8, the divalent ion  $HPO_4^{2-}$  being dominant.

While van den Honert<sup>6</sup> and McGeorge<sup>7</sup> concluded that the absorption of orthophosphate by higher plants was primarily a function of the concentration of  $H_2PO_4^-$ , Hagan and Hopkins<sup>8</sup> deduced from a kinetic study of the uptake of phosphate by excised barley roots from solutions ranging in pH between 4 and 8 that both ions are accumulated, different mechanisms being involved. Because these experiments were not carried out under sterile conditions, however, micro-organisms could have

contributed to the results obtained and the extent of this contribution is likely to have varied widely at the different pH concentrations examined because of the known sensitivity of bacteria to this factor. The effect of pH on the uptake of oxygen by micro-organisms cultured from roots grown under normal laboratory conditions is shown in Fig. 1; their metabolic rate is much reduced at low pH.

The uptake and distribution of phosphate in young barley plants over a period of 3 h from solutions of potassium phosphate containing 0.01 p.p.m. phosphate at pH 4.0, 6.0 and 8.0 were therefore examined under both rigidly sterile and non-sterile conditions by the procedures previously described<sup>2,9</sup>. Although in the absence of micro-organisms the total quantity of ions taken up by the plants and the relative amounts transferred to the shoots varied with pH, the partition of the absorbed phosphate to the roots was similar in all three cases (Fig. 2). In contrast, under non-sterile conditions less phosphate was transferred to the shoots and the partition of the absorbed phosphate in the roots was highly dependent on pH. With increasing pH there was a marked decrease in the incorporation of phosphate into the soluble fraction in the roots and a concomitant decrease in its transfer to the shoots.

It is clear therefore that when the effect of pH on the uptake of phosphate is studied the results obtained reflect not only changes in the relative concentrations of the  $H_2PO_4^-$  and  $HPO_4^{2-}$  ions but also variations in the activity of the attendant microflora. Thus unequivocal conclusions regarding the accumulation of the two ion species by the roots of plants can be drawn only from experiments carried out in the absence of micro-organisms.

I thank Dr R. Scott Russell for his interest in this work.

### Distribution of Dry Matter to Flowers in *Chrysanthemum morifolium*

THE horticultural chrysanthemum (*Chrysanthemum morifolium*) is a short-day plant and normally requires long uninterrupted dark periods for flower induction and development<sup>1</sup>. Plants can be induced to flower in summer if the natural daylength is artificially shortened to less than 12 h by covering the plants with black cloth for part of the day. This practice forms the basis for the production of "all-year-round" pot plant chrysanthemums. Flower quality is of great importance with this type of crop and we have examined the effect of both carbon dioxide concentration and daily light total on the growth and flowering performance of *Chrysanthemum morifolium* c.v. 'Golden Princess Anne', when grown in controlled environments. We have also investigated the distribution of dry matter about the plant, with particular reference to its diversion to flowers.

In the first experiment (January 18–April 13, 1966) growth was followed in an orthogonal experimental design using three levels of light (30, 60 and 90 cal/cm<sup>2</sup>/day—30 cal/cm<sup>2</sup>/day is equivalent to the average daily total of visible radiation received in a glasshouse in the south of England in late October and mid February) and three

concentrations of carbon dioxide (300, 600 and 900 p.p.m.). In the second experiment (September 22–December 13, 1966), the same three light levels were combined with four levels of carbon dioxide concentration (300, 600, 900 and 1,500 p.p.m.). In both experiments, the day temperature was maintained at a constant 65° F and the night temperature at 60° F. Rooted cuttings were grown in a vermiculite/sand/gravel mixture (2 : 1 : 2 by volume) in pots irrigated daily with a complete nutrient solution. The normal daily cycle consisted of 8 hours of light from "warm-white" fluorescent lamps followed by 16 h of darkness, although for the first week of growth the plants also received 5 h of low intensity light from tungsten filament lamps given in the middle of the dark period—a non-inductive treatment. One week after the beginning of short day treatment, the growing point and its surrounding leaf initials were removed from each plant to induce the formation of lateral branches. After a further three weeks, the weaker lateral growths were removed and the axillary flower buds on the remaining laterals were also removed to leave a single terminal flower on each branch. The several flowers on any one plant all developed at similar rates. Samples were removed from each treatment at frequent intervals<sup>2</sup> and lamina area and dry weight, and the dry weights of the stems plus petioles, roots, and flowers were determined. The number of flowers per plant was also recorded and the average stage of flower development per plant was assessed using the arbitrary scale given in Table 1. On average the plants passed through three stages of development every two weeks.

Table 1. SCALE OF FLOWER DEVELOPMENT

0. Vegetative apex
1. Flowering apex
2. Flower bud less than 10 mm diam.
3. Flower bud greater than 10 mm diam.
4. Florets visible on the capitulum
5. Florets coloured
6. Florets expanding
7. Few outer florets fully expanded
8. Flower open
9. Flower fully open

Flower weight and the rate of flower development were both affected by treatment and these responses will be discussed elsewhere. In order to assess the effect of treatment on flowering performance and to compare plants of different sizes we made use of the flower weight ratio—the weight of flowers divided by the total plant dry weight. This ratio gave a measure of the proportion of the resources of the plant which had been diverted to reproductive organs. The treatments which produced the heaviest plants also produced the highest flower weight ratios at any moment in time. These treatments, however, also tended

Fig. 1. The relationship between flower weight ratio and stage of flower development in *Chrysanthemum morifolium* c.v. 'Golden Princess Anne'. Experiment began January 18, 1966. Each point represents the mean of three plants. Open circle, open triangle, open square, 30 cal/cm<sup>2</sup>/day; hatched circle, hatched triangle, hatched square, 60 cal/cm<sup>2</sup>/day; solid circle, solid triangle, solid square, 90 cal/cm<sup>2</sup>/day; open circle, hatched circle, solid circle, 300 p.p.m. CO<sub>2</sub>; open triangle, hatched triangle, solid triangle, 600 p.p.m. CO<sub>2</sub>; open square, hatched square, solid square, 900 p.p.m. CO<sub>2</sub>.

Fig. 2. The relationship between flower weight ratio and stage of flower development in *Chrysanthemum morifolium* c.v. 'Golden Princess Anne'. Experiment began September 22, 1966. Symbols as in Fig. 1. Open diamond, hatched diamond, solid diamond, 1,500 p.p.m. CO<sub>2</sub>. Each point represents the mean of three plants.

to produce the most rapid rates of flower development and, when this factor was taken into consideration by plotting the flower weight ratios against the average stage of flower development, the relationship shown in Figs. 1 and 2 was obtained. Thus the proportion of total dry matter that was diverted to flowers as a whole was highly correlated with their average stage of development. This relationship was independent of treatment and of total dry weight, which was in the range 5–20 g at the final harvest and appeared to be independent of flower number, which ranged from three to eight per plant.

This correlation has relevance to horticultural practice. If it is generally applicable, then it is apparent that the weight of "open flowers" per plant can only be increased by increasing total plant dry weight. Although at the "open flower" stage the flower weight will represent the same proportion of the total weight in a small plant as in a large plant, small plants can only have a small weight of flowers. Because the relationship was apparently independent of flower number, improved weight or quality of individual terminal flowers can be obtained if all the axillary flower buds which would compete for the proportion of dry matter available are removed as early as possible. This provides the basis of the disbudding treatment used to produce large blooms for commerce or showing. The further reduction of flower number by the removal of strong lateral branches would significantly reduce total dry weight, but we have no information regarding the effect of removing some terminal flowers and leaving the leaves and stems.

The two figures correspond exactly at flower stage 8 but not at the lower values; the flower weight ratio is marginally lower for any flower stage in the first experiment. This discrepancy may either reflect a true difference between occasions or a small change in the subjective assessment of these intermediate stages of development. It was apparent, however, that close control over the diversion of dry matter to flowers existed in the chrysanthemum when grown under these conditions.

## Interaction of CCC and Water Deficit on Wheat Yield

2-CHLOROETHYLTRIMETHYLAMMONIUM chloride (CCC) shortens wheat straw and is used to lessen losses caused by lodging, but there is good evidence that it sometimes also increases the yield of wheat in other ways. For example, Humphries, Welbank and Witts<sup>1</sup> reported an increase of 5 per cent in the grain yield of 'Phoebus' spring wheat after spraying with either 2.5 lb. or 5 lb./acre of CCC at the five leaf stage, although plants in the untreated plots did not lodge. They tentatively attributed the increase to the better penetration of light through the crop enabling more ear-bearing shoots to survive.

This explanation, however, seemed less likely in view of our experience in 1965 when CCC did not increase yield, except perhaps in plots with closely spaced rows (4 in.), although the straw was shortened by CCC as much as in 1964.

In 1966, increases in yield were obtained in two experiments although again lodging in untreated plots was negligible. In the first, CCC in amounts of 2.5 lb./acre at the five leaf stage was applied to 'Kloka' wheat in the irrigation experiment at the Woburn Experimental Station. A wheat section of this experiment consisted of three blocks of two plots with one plot irrigated in each block. CCC was applied to half plots and four amounts of nitrogen fertilizer (0.4, 0.8, 1.2, 1.6 cwt./acre) partially confounded with CCC on quarter plots. During a dry period of 2 weeks from May 25, 2 in. of irrigation water was applied. This was beneficial especially in combination with large nitrogen dressings and increased grain yield estimated from sample areas of 2.8 m<sup>2</sup>/plot by 10 cwt./acre on plots receiving 1.2 or 1.6 cwt. of nitrogen (Table 1). CCC had little effect on the yields from the irrigated plots, but it increased yield from the unirrigated plots by 6 cwt./acre. These increases in yield were associated with more ear-bearing shoots (estimated from a weighed sub-sample from the area of collection) and greater grain weight/ear (Table 1). Plants treated with CCC seemed to lose fewer shoots than untreated plants during a dry spell in the period around ear emergence and so yielded more. More grains on each ear of plants treated with CCC more than offset the smaller weight of 1,000 grains, and so gave a greater grain weight for each ear. The regression of yield on shoot number showed that survival of an additional twenty shoots/m<sup>2</sup> increased grain by 1.9 cwt./acre. In an experiment at Rothamsted in 1966 with 'Kloka' wheat given four quantities of fertilizer (0, 0.8, 1.6, 2.4 cwt. of nitrogen/acre), although untreated plots did not lodge, CCC again increased yield by an average of 2 cwt./acre—a result very similar to that obtained in 1964.

Observations that CCC increases root growth have mostly been made on plants growing in pots<sup>2</sup>, but Hanus<sup>3</sup>

Fig. 1. Mean weekly soil deficits (in.) from May to July. a, Rothamsted, 1964; b, Rothamsted, 1965; c, Rothamsted, 1966; d, Woburn, 1966; ee, time of ear emergence.

points out that root growth in pots may be restricted and the true effect of CCC on root growth can be judged only in the field. We found in both 1964<sup>1</sup> and in 1965 (Table 2) that the weight of root recovered by hand-pulling, that is roots in the top layers of soil, is larger from plants treated with CCC than from untreated plants. Hanus<sup>3</sup> showed that whenever it was applied CCC increased root growth at all depths, and he claimed that the larger root systems were associated with larger yield. Many drought-resistant plants are characterized by relatively large root systems<sup>4</sup> and CCC may have increased yield in our experiments because it increased the amount of roots and so enabled more shoots to survive dry periods when shoot number was declining, especially about the time ears were emerging.

Figures supplied by Dr H. L. Penman show that moisture deficits after ear emergence increased in 1964 and 1966 but decreased in 1965 (when CCC did not increase yield in a normally spaced crop), see Fig. 1. This suggests that drought is most critical near the time of ear emergence and that CCC counteracts it by increasing the size of the root system. The greater effect of CCC at Woburn may be because the sandy soil there is more subject to drought than the clay soil at Rothamsted.

## Selective Phytotoxicity of 2,4-Dichloro 6, (o-chloroanilino)-s-triazine ('Dyrene') to *Cirsium arvense*

WHILE carrying out a fungicide field experiment for the control of *Botrytis cinerea* on strawberries in an area heavily infested with creeping thistle (*Cirsium arvense*), it was noted that approximately 50 per cent of the thistles in certain plots died within 2-3 days of making the first

fungicide application. The plots concerned appeared to be those treated with 'Dyrene' (2,4-dichloro 6, (o-chloroanilino-*s*-triazine). Neither the crop nor any other weed growing in this area showed phytotoxicity. The effect on the thistles, which were 6 in. tall at the time of spraying (June 1966), consisted of a rapid browning, general discoloration and necrosis of all emerged parts.

This extreme degree of selectivity eventually led to a series of greenhouse and field experiments being conducted in the United Kingdom and by various collaborators in Canada. The results of these field screening operations, all treated at the arbitrary rate of 2 lb. active ingredient/acre, are summarized in Table 1.

The pattern of results given in Table 1 shows that the activity of 'Dyrene' on thistles is an "all or nothing" effect and that the ratio of resistant:susceptible individuals varied immensely from one site to another in both the United Kingdom and Canada. This ratio was found to vary within a few yards on a single field—a pattern which obviously suggested the existence of strains of *Cirsium arvense* which responded differently to 'Dyrene' treatment. Attempts to relate resistance and susceptibility to morphological differences between thistles have so far not been successful although it is possible that in Canada the response may parallel the two varieties of *Cirsium arvense* described by Saidak<sup>1</sup> as 'Horridum' and 'Mite'. These varieties are morphologically distinguishable and accordingly the response of a given population of thistles to either 'Dicamba' or 2,4-DB can be predicted.

A preliminary survey was made in an attempt to correlate resistance or susceptibility to the sex of the specimen concerned, but this proved negative and seeds harvested from both resistant and susceptible specimens were found to be viable. Neither the dosage of 'Dyrene' used nor the growth stage when the chemical was applied had any effect on this pattern in that resistant populations tolerated dosages of up to 2 lb. of active ingredient/acre, while 1 oz./acre killed the susceptible specimens and even spray drift was sufficient to show a marked scorching effect.

Initial observations suggested that effects could be detected outside the sprayed plots even when drift was practically eliminated by the use of screens and this might imply that translocation or systemic transfer of the chemical occurred by way of the rhizome. Such possibilities are obviously of interest, but any attempt to analyse this problem was hampered by the fact that susceptible and resistant specimens could not be distinguished before treatment. By careful dosing, however, it has now been possible to isolate two clones which respond differently to this chemical.

## Particulate Localization of Acid Phosphatase in Fungi

CYTOCHEMICAL demonstrations of the activity of acid phosphatase have been made in fungi<sup>1-3</sup> and it is generally considered that the distribution of this enzyme in these organisms is of a particulate nature. The lysosomes of animal cells are believed to contain all the cytoplasmic acid phosphatase<sup>4</sup>. Although these granules have not yet been conclusively demonstrated in fungi the localization of this enzyme in the mitochondrial fraction of freeze-substituted centrifuged hyphae<sup>2</sup> is consistent with its distribution in the light mitochondrial or lysosomal fraction of animal cell homogenates.

*Botrytis cinerea* Fr. was grown on coverslips for 2 days at 25° C on disks of malt extract agar. The disks were removed and the unfixed tissue adhering to the coverslips was used directly or after fixation for 1.5 h at 0°-4° C in cold acetone.

The Gomori<sup>5</sup> lead nitrate method gave excellent results with incubation periods of 1.5-2 h at 37° C. The modified lead nitrate method<sup>6</sup> gave similar results with incubation times of 15-30 min, but the particles were paler and more finely delimited. The standard coupling azo dye technique (Fig. 1) using a substrate of sodium  $\alpha$ -naphthyl phosphate and incubation times of 10-20 min at 37° C gave good localization in the presence of 7.5 per cent polyvinyl pyrrolidone when coupled with fast garnet GBC salt. The post-coupling azo dye method<sup>7</sup> gave good results with sodium 6-benzoyl-2-naphthyl phosphate as the substrate and an incubation time of 1-1.5 h using fast blue B salt as the coupling dye. The appropriate controls for these methods gave negative results.

These results were indicative of the particulate localization of acid phosphatase within the cytoplasm. After short periods of incubation no staining or only faint staining was obtained; prolonged incubation resulted in diffuse staining and some nuclear staining. With optimum incubation times spherical particles 0.2-1.0  $\mu$  in diameter were visible and these varied in numbers in each cell from less than ten to more than 100. It was also shown that the cytoplasm contained particles of the same size and numbers as the acid phosphatase particles which absorbed neutral red, fluoresced an orange colour in acridine orange at neutrality and possessed low contrast against the cytoplasm when examined with the phase contrast microscope.

Similar results were obtained using a number of other fungi including *Neurospora crassa* Shear and Dodge, *Sistotrema brinkmannii* (Bres.) Rogers and Jackson, *Cunninghamella elegans* Lendner, *Pyronema omphalodes* (Builliard) Fuckel and *Penicillium notatum* Westling.

Fig. 1. Particles containing acid phosphatase in *B. cinerea*, stained by the standard coupling azo dye method.

Although it is now generally considered that the lysosomes contain all the acid phosphatase of animal cells, it is apparent that the spherosomes of bulb scales of *Allium*<sup>8</sup> and of root tips of a number of grasses<sup>9</sup> and cytoplasmic particles in root tissues of *Vicia faba*<sup>10</sup> contain acid phosphatase and as such are possibly related to the lysosomes. The present work clearly demonstrates that fungi also possess particles containing acid phosphatase within the cytoplasm. Although the various types of particle shown in this work were not identifiable with each other, it is apparent that fungi possess particles with certain attributes in common with the lysosomes.

## ANIMAL BEHAVIOUR

### A Maturation Factor in Spontaneous Alternation

WHEN it is given consecutive trials in a *T* maze, the rat will typically enter one arm of the maze on the initial trial and the opposite arm on the second. This phenomenon has been termed "spontaneous alternation"<sup>1</sup>. Lesions to the hippocampus or the administration of cholinergic blocking drugs, processes which have been found to interfere with learning and remembering, also impair spontaneous alternation<sup>2,3</sup>. This suggests that the rate at which an animal spontaneously alternates could be a function of its ability to acquire and retain information. The present investigation was concerned with spontaneous alternation as a function of age. It is well established that the ability to learn and remember develops with maturation<sup>4-6</sup>. We postulated a parallel development for alternation performance.

Four groups of ten Sprague-Dawley albino rats served as subjects. At the commencement of testing the subjects in each group were respectively 20, 40, 60 and 80 days old. Three *T* mazes, proportioned to the sizes of the rats, were used. The 20 day old group was tested in a maze with arms 24 cm long, 10 cm deep and 7.5 cm wide; the 40 day old group in a maze with arms 30 × 12.5 × 10 cm, and the 60 and 80 day old rats in a maze with arms 45 × 15 × 15 cm. In each case the stem of the *T*, separated from the rest of the maze by a guillotine door, served as a starting box.

The subjects were given two trials daily for 3 days. A typical trial was as follows: the rat was placed in the starting box, the guillotine door was raised and the rat was allowed to enter either arm of the *T*. A four-footed entry into one side of the maze completed the trial. Within 5 sec of completion of the first trial the rat was replaced in the starting box for the second trial. If a rat failed to enter an arm within 2 min the trial was terminated and results of that day discounted.

The alternation rates for each group, corrected for initial response tendencies<sup>1</sup>, were tested against chance by

chi square. Younger rats alternated randomly (20 day old group, adjusted rate, 53.3 per cent and  $\chi^2$ , 0.02; 40 day old group, adjusted rate, 65.4 per cent and  $\chi^2$ , 0.94). The 60 day old group (adjusted rate, 74.7 per cent and  $\chi^2$ , 3.25,  $P < 0.05$ , one-tail) and the 80 day old group (adjusted rate, 86.7 per cent and  $\chi^2$ , 5.40,  $P < 0.02$ , one-tail) alternated significantly above chance. The rate of alternation was found to be significantly associated with age ( $C = 0.263$ ,  $P < 0.02$ , one-tail). Percentages of failures to leave the starting box within the 2 min limit were calculated for each group: 20 day old, 0 per cent; 40 day old, 16.7 per cent; 60 day old, 10.0 per cent; 80 day old, 13.3 per cent. These percentages did not differ significantly, which suggests that the differences in alternation were not caused by differences in emotionality as reflected in the "freezing response". Investigations with a variety of species have indicated that exploratory behaviour decreases with age<sup>7,8</sup>; thus it seems unlikely that the lower alternation rates of the younger animals were the result of a lessened exploratory drive. It has been found that rats reared in an "enriched environment" perform better on learning and problem solving tasks than rats reared in a "deprived environment"<sup>9</sup>. Unpublished results of mine have indicated that "enriched environment" rats alternate significantly more than "deprived environment" littermates. These findings, together with those of the present investigation, support the suggestion that the ability of the rat to alternate spontaneously depends on its ability to learn and remember.

### Tolerance and Dependence in the Planarian after Continuous Exposure to Morphine

MORPHINE addiction is a phenomenon thought to be limited to higher mammalian species<sup>1</sup>. Recent work, however, suggests that it may be possible to produce an addiction syndrome in organisms lower on the phylogenetic scale.

Wikler<sup>2</sup> demonstrated a model of addiction and relapse in rats based on two-factor conditioning theory. Similarly, Nichols and Davis<sup>3</sup> and Weeks<sup>4</sup> have used instrumental techniques to maintain morphine self-administration in rats.

A number of investigators have reported conditioning in the planarian by both classical and instrumental methods<sup>5-8</sup>. These results, while controversial<sup>9</sup>, suggest that if the flatworm can be conditioned, it can be addicted. If addiction can be produced in the planarian, this organism, with its simple ganglionic nervous system and profound capacity for regeneration, would provide a useful system in which to study the cellular changes that accompany the addicted state.

This article presents the results of attempts to produce and measure two aspects of the addiction syndrome, tolerance and dependence, in the planarian, *Dugesia dorotocephala*.

Adult *D. dorotocephala* were kept in individual Petri dishes in 30 ml. of reconstituted distilled water<sup>10</sup>.

The time taken to swim from the centre of a circle of light to the circumference was used as a measure of the worm's performance. A planarian is negatively photophobic and will swim rapidly and directly to the edge of the circle to avoid light. In concentrations of morphine sufficient to depress the animal, the transit time is increased by slow swimming or an erratic path. Tolerance can be defined, then, by the return of function towards normal in a previously depressed animal, as measured by decrease in transit time. Dependence is defined as the deterioration of swimming performance when morphine is withdrawn.

A circle with a radius of 5 cm was drawn on a table top. A tensor-lamp was placed 18 in. above this. A shutter was interposed between the lamp and the target. Worms to be tested were placed individually in a 12 in. 'Pyrex' plate filled with 150 ml. of the test solution and allowed to incubate for 15 min.

The worm was then moved to the centre by moving the plate, the shutter opened, and the transit time to the circumference of the circle recorded. Five consecutive trials were run on each subject. If a worm failed to reach the circumference after 120 sec, the trial was scored as 120 sec.

All test solutions were adjusted to pH 7 with dilute sodium hydroxide.

**Experiment I: Tolerance.** Before exposure to the drug, the transit times of all worms in water were recorded. The mean transit time was 29 sec ( $\pm 15$ ). Trials were then carried out in morphine, 0.5 mg/ml. The experimental animals were then returned to their home dishes into which 30 ml. of morphine solution, 0.4 mg/ml., had been placed. Control worms were handled identically but returned to water between trials. After 8 days' exposure to morphine, the subjects were run again under the same conditions.

**Experiment II: Dependence.** Nine experimental worms were raised in morphine, 0.3 mg/ml., for 15 days; then in 0.4 mg/ml. for 8 more days. Their transit times in morphine, 0.5 mg/ml., were then measured. Subjects were then returned to morphine, 0.4 mg/ml., for 20 more days.

After 43 days' exposure to morphine, the worms were abruptly withdrawn by placing them in water for 60 min. After withdrawal, their transit times in water were measured. Control worms were treated identically, but were raised in water.

**Tolerance:** Table 1 presents the transit times in morphine of eight experimental and four control worms before and after 8 days' exposure to morphine, 0.4 mg/ml. A significant decrease in transit time after exposure to morphine is apparent, suggesting the development of tolerance. Tolerance is also demonstrated after 23 days' exposure in experiment II.

**Dependence:** On withdrawal from morphine, experimental subjects showed a significant increase in transit time. Before withdrawal, all worms were observed to be swimming rapidly and smoothly in their dishes. Of the

nine experimental worms run after withdrawal, only two showed any spontaneous swimming movements in water. Seven adhered to the dish and became crinkled in appearance, refusing to move even when stimulated gently. This behaviour persisted for periods of time varying from 7 to 20 h before normal swimming was observed. Control worms continued to show normal swimming behaviour throughout the period of observation.

It appears that planarians, under the proper experimental conditions, are capable of developing tolerance to, and dependence on, the narcotic properties of morphine.

An alternative explanation is that the experimental subject responds to morphine as a strong, non-specific novel stimulus, and that the subject's improved performance after continuous exposure is a non-specific adaptation to that stimulus. While this position can also be used to account for the deterioration of performance on withdrawal from morphine, the striking effects of withdrawal make this an unlikely assumption in the latter case.

This investigation was supported in part by a fellowship and a general research support grant from the US Public Health Service.

### Imprinting: Reversal of a Preference established during the Critical Period

Two distinctive features of "imprinting" originally emphasized by Lorenz<sup>1</sup> were that there was a critical period in which the preference for a particular species was established and that the preference established during this period was permanent and could not be changed by subsequent experience. These two features have been reiterated by Hess<sup>2</sup>, who has added a primacy-recency feature, claiming that the first imprinting experience has priority over a subsequent one. These features of imprinting have been questioned by Sluckin and Salzen<sup>3</sup>, who treated imprinting as a perceptual learning phenomenon in which the sensitive period is experience dependent and the stability of an imprinted preference is dependent on the amount of experience. More recent reviews by Sluckin<sup>3</sup> and Bateson<sup>4</sup> have supported this view. In particular the perceptual learning view of imprinting has been developed into a neuronal model hypothesis of imprinting by Salzen<sup>4</sup> and it predicts that object preferences established by the imprinting process should be subject to reversal given sufficient exclusive and enforced experience of new objects after the end of the so-called critical period. The present experiment demonstrates a reversal of this kind.

The experiment used Cornish  $\times$  White Rock chicks hatched in separate boxes and transferred when 12-18 h old to isolation rearing cages. In the centre of each cage separate from the sources of food, water and heat, there was either a dark blue or a green cloth covered paper ball about 5 cm in diameter and hanging approximately 3 cm

\* Seven animals had mean times of 120 sec. Two had mean times of 44.4 and 42.4 sec respectively.

above the floor. The chicks quickly became strongly attached to the balls, spending much time beside them, and interacted with the balls by pushing, pulling, and pecking them. After three days (12 h light/dark cycle) the chicks were tested for their preference between blue and green balls. The balls were hung midway on opposite long sides of a box (45 × 90 cm). The chick under test was placed in the dark at the mid-point of a short side, a lamp was switched on above the box, and the chick was given 2 min in which to go to and stay with one of the balls. A preference was recorded if the chick after reaching a ball either contacted it, pecked and pulled it, and/or gave pleasure calls, or stayed close (1 in.) beside the ball and was silent or pleasure calling. The trial was ended when either of these criteria was reached or at the end of 2 min. The light was switched off, the chick was returned to a holding box and the positions of the objects were reversed ready for the next trial. Ten trials were made with each chick. After testing the chicks were returned to their cages and the balls exchanged so that each chick now had a new and different coloured ball. The chicks began to respond to the new balls on the same day. Three days later the chicks were again tested for their preference between green and blue balls. Then they were returned to their cages for a further three days but this time without any balls present. Finally, a third preference test was given. In this way twelve chicks were imprinted with a blue ball and then given reversal training with a green ball, while ten chicks were tested in the opposite manner.

The results are shown in Fig. 1 in terms of the mean number of responses made by the chicks to each ball in each preference test. The two colour treatments are combined because they were nearly balanced and gave similar results. The results show that at the end of the first 3 days the chicks had an almost exclusive preference for their familiar coloured ball ( $p < 0.01$ , Wilcoxon test). After the second three day period, this preference had been reversed ( $p < 0.01$ , Wilcoxon test). At the third test the new preference was maintained or even slightly increased because the responding to the preferred ball had increased significantly since the second test ( $p < 0.02$ , Wilcoxon test). Twenty-one of the twenty-two chicks made more responses to their familiar ball on the first test. On the second and third tests eighteen and seventeen of these twenty-one chicks made more responses to the newly experienced ball.

There can be no doubt that the period in which the first ball was experienced included any possible critical period for imprinting in chicks. The experience began 18 h after hatching, and Hess<sup>5</sup> has claimed that this period reaches its peak at this time for chicks. Furthermore, the second ball was experienced well after the end

of the critical period of 24 h determined by Hess. Many studies<sup>3</sup> have shown that domestic chicks imprint with objects when exposed to them within the first 3 days after hatching. Thus the experiment shows that a strong preference established during this imprinting period can be completely reversed by subsequent experience. It also shows that this reversal was maintained intact after a period in which forgetting of both objects could have occurred. It cannot be said therefore that learning which takes place after the imprinting period is more rapidly forgotten than the learning during the imprinting period. Thus it would seem that the most recently learned preference predominated contrary to Hess's<sup>2</sup> claim of a primacy effect in imprinting. The recent test by Kaye<sup>6</sup> of a primacy effect gave an equivocal result, probably because of the very short training periods involved. The present test used stimulus objects that differed only in colours that were known from pilot studies to be equally easily learned and discriminated by chicks. The design was balanced for colour and similar results obtained with either colour. The training periods were long and the resulting preferences very strongly developed. Finally, the behaviour in the tests involved patterns of social interaction as well as the simple approach response. This study therefore represents the first closely controlled laboratory demonstration of reversibility of imprinting in precocial birds. It confirms the predictions of the neuronal model hypothesis of imprinting and agrees with the field observation of Steven<sup>7</sup>. In the field study by Schein<sup>8</sup> there appeared to be evidence for an irreversible preference for humans among human imprinted turkeys. It should be noted that these turkeys were always able to see humans as well as their later flock companions. Under these circumstances the neuronal model hypothesis would not necessarily predict a change in preference. The present demonstration of reversibility of imprinting in chicks agrees with the demonstration of a reversible social attachment in lambs<sup>9</sup>. Similar results have been obtained with a shape discrimination and a full account will be published elsewhere.

## PSYCHOLOGY

### Frustration Tolerance and Incidental Learning as Determinants of Extinction

Two theories currently exist to explain the retarding effect of partial reward on the extinction of a learned behaviour. Amsel<sup>1,2</sup> has suggested a theory based on the thesis that the shortcomings (non-reward) of a partial reward schedule generate frustration, experience of which reduces the reaction to the frustration induced by extinction. We shall here refer to this as the "frustration tolerance" theory. Sutherland<sup>3,4</sup>, on the other hand, has proposed a theory based on the assumption that partially rewarded animals switch attention more often than con-

sistently rewarded animals and therefore learn about more cues. During extinction the responses to all the cues which the animals have learned about during training have to become extinguished. This suggests that the more cues learned about the longer it takes to extinguish the responses to them. We shall refer to this as the "incidental-learning" theory.

Recent work<sup>5</sup> suggests that the two theories are not incompatible. Thus if frustration diverts attention, animals experiencing frustration during acquisition will learn about more cues, with consequent effects on extinction rates that are compatible with both theories. This view is supported by the finding<sup>5</sup> that when drugs which reduce frustration are administered during acquisition, they can inhibit incidental learning in partially rewarded rats. Extinction of the learned behaviour was faster in these rats than in the placebo controls, but this result does not indicate whether the effect of the drug on extinction results from a reduction of frustration tolerance, or from an inhibition of incidental learning. The experiment reported here was designed to distinguish between these two possibilities.

The subjects were forty adult hooded male rats, which were 90 days old at the start of the experiment. They were maintained on a schedule in which they were deprived of food for 22 h per day but allowed *ad libitum* access to water. The animals were subjected to a pre-training course during which they were trained to make the instrumental response in a Grice box from which the stimuli had been removed. The subjects were then allocated to four groups, matched for performance in pre-training. During training each rat was run for ten trials per day, with a mean inter-trial interval of 10 min. Rewards consisted of access to food for 10 sec.

The training procedure for the four groups is summarized in Table 1. The subjects were transferred from part 1 to part 2 when they reached an individual criterion of eighteen out of twenty successive correct choices. Groups 2 and 4 were then run on a second problem until they reached the same criterion. Groups 1 and 3 were overtrained on the original problem until groups 2 and 4 reached their second criterion. Thus all groups had the same number of training trials. The cues which the animals had learned during training were extinguished and the animals run until they reached a criterion of two "no-runs" in succession. When the animals took more than 2 min from start to choice criterion a "no-run" was scored.

The mean number of trials to the extinction criterion is shown in Table 2. These results show that there was no significant difference in resistance to extinction between the one and two cue consistently rewarded groups, or between the one and two cue partially rewarded groups, but that there was a very large difference (that is to say, there was no overlap in the range) between consistently

rewarded and partially rewarded groups. Moreover, the percentage of correct choices made during the last twenty extinction trials (Table 2) indicates that there is no significant difference between the one and the two cue groups on this criterion, but a very large difference between consistently rewarded and partially rewarded groups.

It is difficult to see how the results can be accounted for on Sutherland's hypothesis because there are no apparent differences in resistance to extinction between groups which learned about one or two cues during training. On Amsel's hypothesis no such difference would be expected, except that the two cue groups might have experienced some frustration in learning the second problem. Because training Part 1 took 180 trials and Part 2 took only eighty trials, however, it is evident that few incorrect choices can have been made in learning the second problem. Whatever extra frustration was experienced may be reflected in the non-significant difference between the magnitude of the scores for the one and two cue groups (Table 2).

The finding that the partially rewarded groups were much more resistant to extinction than the consistently rewarded groups can be accounted for by Amsel's theory, on the basis of the differing degrees of frustration experienced during training. On Sutherland's theory, it can be accounted for on the basis of frustration induced irrelevant learning. It seems difficult, however, to maintain the latter view in face of the lack of differentiation between the one and two cue groups. If Sutherland's<sup>3,4</sup> hypothesis were correct, the more cues learned about during acquisition, whether or not frustration is involved, the greater would be the resistance to extinction, on the assumption that all cues learned about have to be extinguished separately, and that this process takes longer even if each cue is learned about to a lesser extent. The most reasonable conclusion is that resistance to extinction is determined primarily by frustration tolerance, and that the demonstrable<sup>5-7</sup> correlated incidental learning is a side effect which plays no part in extinction. Such a view would be consistent with the finding<sup>6</sup> that competing responses, artificially facilitated during extinction, do not affect the extinction rate.

## Attempts to improve Perceptual Clarity in an Aircraft Display

A VISUAL display recently developed for aircraft<sup>1</sup> offers three principal improvements for pilots. First, it is projected at windshield eye-level so that the pilot need make fewer changes in the direction of visual gaze (from "head-up", outside the cockpit, to "head-down", inside). Second, it is collimated, so that the pilot can fixate both display and external view with his eyes accommodated to physiological infinity. Third, the display is capable of presenting the simplest visual picture compatible with the current task of the pilot, so that it can exploit the unique ability of man to follow pictorial information without burdening him with rapidly changing numerical data. Fig. 1 shows the three basic elements of such a display.

A dot at the apex of a triangle consisting of four lines tells the pilot, usually from computer sources, where he is being asked to fly. The centre of a small circle informs him

where he is flying at the moment. The two halves of a broken line give him information about his aircraft's attitude relative to the horizon. His basic task in directed flight is thus to capture a dot at the centre of a circle while paying attention to aircraft rolling and pitching. The display is appreciated so naturally that pilots with no previous relevant experience can readily control both displacements in height and heading as well as rotations in roll and pitch simultaneously.

To evaluate possible changes in display element geometry, four experiments were run, each asking between eight and twelve jet pilots to control simulated flight missions in an aircraft cockpit mockup. Display changes were presented according to statistical designs aimed at balancing out any sequence effects such as learning and fatigue. As well as normal measures of system error, pilot opinion was also obtained based on the assumption, previously justified in aircraft handling studies, that trained pilot opinion is an indication of the effort expended in achieving a measured accuracy<sup>2-4</sup>. Response times to occasional warning light signals gave a measure of the general attention level of the pilots. Fig. 2 shows the display element varieties and conditions.

By any operational criterion, a dot to indicate flight commands was entirely satisfactory, but a small circle allowed even greater precision. Clearly, it has less possible displacement inside the larger circle which denotes the current flight situation. By analogy, one would expect a perfectly fitting cross to be still superior, but this was not the case. Pilots complained that when demands were satisfied, the cross combined perceptually with its containing circle, leaving them in some confusion as to which of the two elements was in their control.

Adding stub wings to the circle representing the current flight situation allowed pilots to identify control more easily with this element, because it now resembled a simplified aircraft sketch. In addition, such stub wings permitted roll control with less effort, by improving roll angle perception. The length of wing, however, turned out to be inconsequential.

Removing the four-line triangle which moves in formation with the flight command dot proved detrimental to performance and unpopular with pilots. Replacing this element with any one of the three illustrated was without effect on accuracy or opinion, however. Here is a second

Fig. 1. The basic display. *a*, The aircraft is in straight and level flight with all demands satisfied. The position of the numerical height scale, when added, is at the top right-hand side. *b*, The aircraft is straight and level. The situation requires a climbing turn to starboard. *c*, Correctly following a demand to execute a descending turn to starboard. *d*, Climbing and straight. Demand to execute a descending turn to port.

Fig. 2. Varieties of display elements and additions. *a* and *b*, The two halves of the element denoting "where to fly". 12 possible combinations. *c*, Elements denoting "where you are flying". *d*, Range scales, showing distance to go (up to 12 miles) to runway, radio beacon, or target.

case of a symbol change producing no observed effect on the perceptual quality of the whole figure.

None of the three range scales emerged as overall best for pilots trying to control distance to go or closing speed. The circular one was preferred, probably because it surrounds the central tracking task at a set distance whatever value it indicates, and allows pilots to capitalize on clock familiarity if, as here, a maximum indication of 12 miles is appropriate.

The addition of a numerical height scale (at the top right of the display) did not appreciably detract from tracking accuracy, and allowed pilots to control as directed while retaining the ability to check actual aircraft height as a safety precaution without looking down at conventional instruments. Such a finding supports the impression that a pictorial display is easily assimilated, and puts relatively small informational demands on the perception of the pilot.

Clearly, this is a difficult experimental area. The lack of a quantified perceptual theory means that the psychological work required of pilots by the addition or modification of a given visual stimulus cannot be predicted at all well. There remains the distinct possibility that several perceptually equivalent displays exist, each one perhaps offering some electronic or servicing advantage over the present one.

## BOOK REVIEWS

### TEACHING ENGINEERING

#### **Engineering at Cambridge University, 1783-1965**

By T. J. N. Hilken. Pp. xi + 277. (London: Cambridge University Press, 1967.) 45s. net.

IN recent years there has been much public discussion concerning engineering education in this country. Important decisions have been taken by the government and are still being taken. Universities, too, are faced with important decisions. It is therefore fortunate that Captain Hilken, administrator of the Cambridge engineering laboratory, has given us a history of the development of engineering at Cambridge which shows us that many of the problems facing us today have already existed in the past, and how they have been solved in what is probably the most important and successful centre of instruction in England.

Captain Hilken traces the pre-history of engineering in Cambridge back to the Jacksonian Chair. It was the intention of the founder that the holder of this chair should not only enquire into "those things which we cannot be without and on which not only our well being but our very existence in the world depends", but also engage in "something in the way of experiment on the subject undertaken". In particular, he wants him "to have an eye more particular to that opprobrium medicorum called the Gout" and hopes that he will find a cure. Hilken gives a detailed history of the foundation of science chairs in Cambridge, showing how it arises out of the scientific climate created by Newton. It was the first holder of the reformed Jacksonian Chair, Isaac Milner, who started the study of what would now be called engineering, and installed lathes, air pumps, furnaces, electrostatic appliances and so on, and the tradition was continued by William Farish and Robert Willis.

In the eighteenth century the university had fallen into a state of decay, and Hilken traces the history of reform from within, culminating in the appointment of Prince Albert as Chancellor in 1847, which came, however, too late, so that, to the disappointment of the latter, Parliament intervened.

This was perhaps the most crucial period for engineering in Cambridge; the subject had been taught in King's College, London, since its foundation in 1831, likewise in University College, London, where a chair in Civil Engineering was established in 1841. The country had fallen behind Germany, where the creation of technical universities had laid the foundation of German pre-eminence not only in technological education but also in scientific engineering. Hilken's book forms a most useful factual guide to the history of the developments in Cambridge, opening the way for further study of the social history of the pattern of decisions made in England. There were always many in the older universities who argued that engineering education should be developed in industrial areas, for the benefit of the region; many thought that engineering was not an academic subject worthy to be taught at Cambridge or Oxford.

There was great resistance to the creation and operation of workshops. The controversies around James Stuart, 1843-75, first professor of mechanism and applied mechanics, who established mechanical workshops in Cambridge make fascinating reading. Stuart supplied the money needed from his own private means. The workshops were run not only for the instruction of students but also

for profit, and this led to difficulties. It was the strong Newtonian tradition in Cambridge and the sound judgments of the great physicists and mathematicians there that saved the cause of engineering in Cambridge. It may be possible to gather even more information about this than Hilken has done, who does not aim at a work of history in the wider sense but rather at a "biography" of the engineering department.

Right up to the present time the case for engineering teaching and research in Cambridge and Oxford had to be argued; for example, in 1956, the general board of the University of Cambridge published a report containing the suggestion that the teaching of applied sciences might best be left to universities in industrial areas. Professor Baker at that time called this statement a gratuitous blow to those in this country who were working with an eye to national needs and to the development of a proper balance in university education. The remarkable growth and flowering of engineering in Cambridge owe much to private munificence, not only from outside sources ranging from Lord Nelson of the English Electric Company to Sir Dorabji Tata, the Indian industrialist, but also to private funds expended by professors and teaching staff.

The question as to what should be taught in engineering courses has been vigorously discussed for a long time. From the days of Stuart, who laid great emphasis on workshop training, to the present time, the syllabus has undergone great changes. The great distinction of Cambridge has been the close connexion of these studies with mathematics and, after a while, to a lesser degree with physics. It is only recently that the development has come to a full circle, and that modern developments again need the grass roots of pure physics. Electrical science has only recently been established as a separate discipline in Cambridge through the efforts of Professor Oatley. The groundwork had been laid largely on the initiative of the Institution of Electrical Engineers.

Despite this development, however, it is characteristic of the Cambridge engineering laboratory that it remained unspecialized, at a time when other universities awarded separate degrees in many proliferating branches of engineering and when technical universities abroad went in for an ever increasing degree of specialization. This trend is now considered in many places here and abroad to have over-reached itself, and a difficult path of return to a broader training, more closely based on physics, is sought. C. E. Inglis, Professor Baker's predecessor, admirably stated in 1941 that "premature specialization cramps the imagination, that a university course of engineering should concentrate on teaching those essentials which, if not acquired at that stage, will never be acquired. The good of education is the power of reasoning and the habit of mind which remains, when all efforts of memorization have faded into oblivion."

It is, however, clear from Hilken's book that a bar to progress was removed when the engineering school freed itself from the mathematical tripos on the suggestion of Bertram Hopkinson in 1912, establishing an examination in mathematics, Part I, suitable for engineers. The problem of how to fit a reasonable degree of specialization into a general engineering course was solved in ever changing ways. The problem is linked with the sorting of men into streams with different abilities.

Hilken's book tells the story of the evolution of Parts I and II of the tripos, of the papers set for the ordinary degree taken by candidates who were not strong enough for the tripos, the splitting into *A* and *B* papers, and the establishment of a slow and fast course, when the subject of engineering studies designed for weaker men was abolished. There is a lot to be learned from Cambridge experimentation with these problems.

The actual content and quality of the teaching are known to me somewhat indirectly. When I came to teach at Oxford after a ponderous German style engineering education, I found the place colonized by such Cambridge

men as R. V. Southwell and E. B. Moullin, and through them became acquainted with the tradition of Cambridge teaching only partly embodied in texts such as Ewing's *Heat Engines* or Lamb's notes on *Electricity*. It seemed like light champagne compared with the dark German beer of my own upbringing.

Even before the First World War the number of engineers in Cambridge was large (about 260), and although the expansion after the Second World War seems very large, it is only a smooth continuation of the pre-war curve through the war gap. The growth of postgraduate studies and research is perhaps more spectacular.

The practice of engineering is always in danger of falling back on crude empiricism when problems get difficult. There does not exist a pre-formed science of physics which needs only to be applied to solve such problems. The physical phenomena underlying the engineering devices have their own distinct laws which, although they are no doubt a sub-set of the laws of physics, are not readily deductible from the basic set. Particularly now, when physics is so much concerned with elementary particles, the nucleus and fine details of spectroscopy, much research is needed to serve industry—research in engineering science which is nothing else but the physics of devices. In Cambridge such men as G. I. Taylor, C. E. Inglis, J. A. Ewing, B. Hopkinson and many others have developed and maintained the tradition of a fundamental approach to engineering problems. We are indebted to Captain Hilken for making available to us many interesting facts from their biographies in the form of a consistent story.

## TALKING BY SATELLITE

### Communication Satellite Systems Technology

By Richard B. Marsten. (Progress in Astronautics and Aeronautics, Vol. 19.) Pp. xx+1,051. (New York: Academic Press, Inc.; London: Academic Press, Inc. (London), Ltd., 1966.) 96s.

THE historically minded may wish to compare this volume, made up of papers given at a Communications Systems Conference of the American Institute of Aeronautics and Astronautics held in Washington in 1966, with the report of an international symposium on space radio communications held in Paris (under the auspices of URSI) in 1961<sup>1</sup>. The problems remain much the same, but progress has been substantial.

Because I could not judge all the diverse contents of this book, I asked colleagues for opinions. They found the sections on Early Bird excellent, the sections on attitude control good, the sections on electronics and antennae informative to those not familiar with the state of knowledge, and a section on deep space optical communication misleading. One colleague concluded: "This is the best book of its kind I have seen, but it could be improved greatly if reduced to about half its present bulk by leaving out the filler sections on 'systems analysis' and the various propaganda articles which introduce nothing that is new and come to no useful conclusions."

To telephone users, the adverse effect of the delay inherent in a synchronous satellite system is important. Barstow's paper gives the impression that this is small while Helder implies that it is considerable. Both papers are based on tests with Early Bird. Psychologists have tackled this problem through a variety of experiments which indicate the effect and its source, not in the delay itself, but in the operation of echo suppressors<sup>2</sup>.

Communication satellites are important because electrical communication is already so important in our lives. They cannot (except through direct broadcast to home receivers) provide a communication service in themselves. Yet, among the authors, agencies and companies

which actually supply communication service to individual users are scarcely represented—indeed, such representation was greater in the 1961 URSI symposium. I believe that this puts discussions of the profitable uses of satellite communication out of perspective.

Marsten asserts that a Titan III-C can launch 3,500 lb. into synchronous orbit, yet he talks of Comsat's plans for 1,200 voice channels; a 3,500 lb. satellite could supply 100 times as many. Pardoe and Steines concentrate on international communication. In the foreseeable future there is bound to be more national than international communication, and 100,000 economical voice channels could have a profound effect in the communication network of a geographically extensive country (or region). In the same paper they find Russia "an enigma", yet say that the Soviet minister of communications "sees that a national system of telecommunications and television can be economically profitable, especially over long distances, and that any new system would not be opposed to existing terrestrial communication systems".

Technologically, satellite communication has progressed greatly between 1961 and 1966. But it remains difficult to integrate this resource with others in providing man with effective communication, national and international. *Communication Satellite Systems Technology*, good as it is, is in many ways a monument to the insularity of that art.

## PHYSICAL GASDYNAMICS

### Physics of Shock Waves and High-Temperature Hydrodynamic Phenomena

By Ya. B. Zel'dovich and Yu. P. Raizer. Edited by Wallace D. Hayes and Ronald F. Probstein. Vol. 1. Pp. xxiv+464. (New York: Academic Press, Inc.; London: Academic Press, Inc. (London), Ltd., 1966.) 144s.

THE second Russian edition of this book was published in 1966. The first volume of the English translation containing rather more than half of the Russian text appeared almost simultaneously. The second half is due to appear in English translation shortly. This is a most commendable feat and is largely due to the close collaboration between authors and editors.

Books on physical gasdynamics are appearing at a steadily increasing rate, but the present text stands out as a particularly valuable contribution. Little time is spent on the elementary background and the authors quickly move into the advanced parts of their subject. This does mean, of course, that few readers can absorb the material without having to consult other texts, and it is therefore difficult to define the audience for which the book is suited. I can, however, fully endorse the editors' remark that it is "well suited for researchers, engineers, students and professors", and might add that they will all find it thoroughly enjoyable.

The first chapter reviews the fundamentals of one-dimensional (one space co-ordinate) unsteady gasdynamics and shock waves, including the effects of heat conduction and viscosity but without going into the detailed effects of varying molecular properties of the fluid.

The second chapter is an excellent introduction to the macroscopic theory of radiation gasdynamics, discussing radiative transfer and its effects on moving fluids. The third chapter is a concise introduction to the equilibrium properties of gases at high temperatures and is followed by a brief chapter on shock tubes and their instrumentation.

The fifth chapter returns to the subject of absorption and emission of radiation with a detailed discussion of spectra and the molecular aspects of the interaction between radiation and matter. Included is an up to date discussion of lasers.

The final chapter in this volume deals with the rates of relaxation processes in gases, including vibration, dissociation, chemical reactions, electronic excitation, and ionization.

Throughout the text the physical approach to the subject dominates, and the theory, although at times necessarily complex, is kept to the simplest level consistent with the requirements of rigour. Particularly pleasing is the continuous supply of numerical examples. This is most important in a subject in which it is difficult to keep track of the orders of magnitude of the quantities involved. There are very comprehensive references to both Russian and western literature.

The text follows very closely the Russian original, except for changes in notation, and the translation is excellent. Any minor modifications appear to have been agreed between authors and editors and in addition a number of editors' comments appear as separate footnotes.

I look forward to the second volume, which will contain chapters on shock wave structure, radiation in shock waves, chemical kinetics, thermal waves, and shock waves in solids, and conclude with a chapter on self similar processes in unsteady gasdynamics.

N. H. JOHANNESEN

## UNIFIED METALLURGY

### An Introduction to Metallurgy

By A. H. Cottrell. Pp. x+548+8 plates. (London: Edward Arnold (Publishers), Ltd., 1967.) 60s. net.

I DID not have the good fortune to be a university student under Dr Cottrell, but I did "sit at his feet" for more than three years while he was at Harwell. During this time I never ceased to be amazed at the clarity of his exposition of complex inter-related ideas and the way, as with fine tweezers, he drew out the significant factors in a problem. After a Cottrell explanation one felt that one understood the whole problem as though it were a simple piece of arithmetic. Unfortunately, a few hours later, one's understanding of the problem became hazy and a tremendous amount of hard work was required to get to the basis of the explanation. After reading this book in a long full day session I am left with the same kind of feelings. The subject is beautifully presented in a clear logical way and for a brief time one understands all those complex problems, but there is a lot of very hard work required to really understand these subjects in depth. To take one example: the idea of lattice defects called dislocations is introduced in a simple, clear and fascinating way, but within the space of a few paragraphs mention is made of slip and twinning dislocations, elastic energy of dislocations, Peierls-Nabarro stress, movement of edge, screw and mixed dislocations, Burgers vectors, Frank-Read source and multiple cross glide, dislocation networks, partial dislocations, and sessile and stair-rod dislocations. In my experience all these topics have to be described in great detail to undergraduate students and the three dimensional concepts may take many months to "sink in". In this sense I do not think that this book provides a satisfactory basic text for students of metallurgy.

The book is, however, an excellent expanded syllabus for a properly balanced metallurgy course. Dr Cottrell has been responsible for many great changes in the teaching of metallurgy and, in particular, has emphasized the need for a basic scientific understanding of the subject. His earlier book *Theoretical Structural Metallurgy* laid

some of the foundations for this approach and, as Dr Cottrell notes in his preface, the science has now become well established and triumphant. He goes on to emphasize the need to reassert the unity of all metallurgical knowledge and to link up this science with the more traditional aspects of the subject. This is not just a pipe dream, for in much of his own work Dr Cottrell has demonstrated the technological and economic potentialities of bringing together the understanding provided by a scientific approach and the broad metallurgical knowledge developed through hundreds of years of experience.

The basic plan of the book is to outline successively scientific principles relevant to metallurgical practice and, in the same chapter, whenever this is appropriate, to relate these principles to practice. To give one example, the chapter on heat and energy starts with some simple thermodynamics, continues by applying these ideas to the combustion of fuels used in metallurgical processes and ends with a purely descriptive account of furnaces used in metallurgical practice. Of necessity some chapters are almost entirely scientific while others are entirely descriptive.

The essential unity mentioned earlier is demonstrated continuously and all metallurgists will find the interplay of disciplines refreshing and illuminating. Once again I must pause to emphasize that in my view it is difficult to teach the subject in this way. The best use of this book would be as essential reading for students who are completing their degree or equivalent course rather than students new to the subject. I would add one qualification to this generalization—the bright, intelligent and enthusiastic student will be immensely stimulated by this book. He will see new dimensions and will be encouraged to search deeper into the basic principles of the subject with the aid of the useful list of further reading at the end of each chapter. The majority, however, could easily fall into the trap of collecting a mass of incoherent facts because they lack the discipline and ability to search out and understand each topic as it is presented.

This book forms a comprehensive survey of metallurgical knowledge covering all aspects of metallurgical science and technology. There is little which has escaped mention and with the aid of a good index it is possible to read up a description of any topic very easily.

DEREK HULL

## SYMMETRY AND FIELDS

### Brandeis University Summer Institute in Theoretical Physics, 1965

Edited by M. Chretien and S. Deser. Vol. 1: *Axiomatic Field Theory*. Pp. xi+516. \$32.50. Vol. 2: *Particle Symmetries*. Pp. xi+691. \$35. (New York: Gordon and Breach, Science Publishers, Inc.; London: Blackie and Son, Ltd., 1966.)

THE Brandeis University Summer Institute in Theoretical Physics is by now an established annual event, and the 1965 session on particle symmetry and axiomatic field theory maintains the high standard we have come to expect from this school.

The first volume covers axiomatic field theory, comprising major expositions, running to 100–150 pages each, on analytic properties of scattering amplitudes in quantum field theory, the connexion between Wightman and LSZ quantum field theory, algebraic aspects of relativistic quantum field theory and relativistic invariance and internal symmetries by, respectively, H. Epstein, K. Hepp, D. W. Robinson and L. Michel. Finally, there is a rather short contribution by R. G. Newton on the three body scattering problem, which does not pretend to mathematical rigour and only just about gets to the Fadeev equations.

All these authors are great experts in their respective and overlapping fields which require considerable familiarity with some highly non-trivial tools in functional analysis and generalized function theory. The lectures of Epstein, Hepp and Robinson are reasonably self-contained, whereas that of Michel requires knowledge of his older Istanbul course on group extension. Hepp's course has the strongest physical basis and can be strongly recommended as an exposition of the Haag-Ruelle scattering theory; by way of introduction non-relativistic scattering is treated in detail. There is good reason to think that the mathematics of these lecture courses will play an increasingly important part in all future physics and that it constitutes the best possible training for the younger theoreticians.

The second volume is much less coherent. There are two highly skilled introductory expositions, "Weak Interactions" and "Symmetries and Elementary Particles", by N. Cabibbo and F. Low respectively. A longish contribution by R. Cutkosky examines "Boot Strapping Models". This is an extremely readable account of a rather obscure subject, obscure because of the widely differing assumptions current in this work. A few of the other contributions have lost some topical interest, such as the review of SU(6) by B. W. Lee and the lectures by T. D. Lee on "Possible C-non-invariance in the Electromagnetic Interactions". Finally, there are lectures with strongly phenomenological flavour, by A. H. Rosenfeld, on "Mesons". This subject is in rapid flux and is constantly being reviewed again. It is of course unavoidable that some of the work presented at summer schools should be overtaken by events before the publication of the lectures. There remains enough first class material in these lectures to justify the issue in book form—that some of the proof reading is sloppy is regrettable.

There are paperback editions of each volume available at \$6.50. S. ZIENAU

## SPECTRA AND SURFACES

### Infrared Spectra of Adsorbed Species

By L. H. Little, with supplementary chapters by A. V. Kiselev and V. I. Lygin. Pp. xii + 428. (London: Academic Press, Inc. (London), Ltd.; New York: Academic Press, Inc., 1966.) 100s.; \$16.50.

THE study of the adsorption of molecules on surfaces is of technological importance in fields such as chemical catalysis, lubrication and adhesion. It is also a subject where scientific knowledge and understanding are still remarkably limited in relation to what is interesting import.

In many areas of chemistry much progress has been made during the past fifty years by the application of the diffraction (particularly X-ray diffraction) and spectroscopic methods of structure determination. The X-ray method depends mainly on the presence of large three-dimensional ordered arrays of molecules, and these are not to be found in monomolecular surface layers. Electron beams can usefully interact with layers a few atoms thick. The method of low energy electron diffraction (LEED) has thus recently made some useful contributions to surface studies; but there is still uncertainty about the interpretation of the results obtained by this technique, and its application appears to be limited to the relatively few cases where very high vacua can be achieved. Applications of spectroscopic methods, which can provide valuable information about the structures and environment of molecules but do not require ordered systems, are therefore of even greater importance in this field than they are elsewhere in chemistry. Most of the spectroscopic methods have made contributions to the study of adsorption. The versatility of infra-red spectro-

scopy, and in particular its ability to obtain information from small samples in all the states of matter, has led to a particularly extensive use of this method on adsorbed molecules.

This book is the first to be published specifically on the spectroscopy of adsorbed molecules. It surveys the results of infra-red studies up to the time of its completion (late 1965).

The interpretation of infra-red spectra of chemisorbed molecules is not an easy matter, partly because some surface species may not find ready analogues among isolated chemical compounds, and partly because there is no guarantee that a particular spectrum does not contain contributions from more than one species. This means that neither the literature itself, nor this comprehensive review of it, makes easy reading for the non-spectroscopist. The author has therefore wisely commenced with an introductory chapter on general principles in which he has also cited some of the typical successes of the method; this should tempt the non-spectroscopic surface chemist to explore the remainder of the book for the significant results in his field of interest. The second chapter provides a clear account of the experimental techniques used in this type of work. The next six chapters are concerned with the spectra obtained from small molecules (carbon monoxide, nitric oxide, carbon dioxide, hydrogen and nitrogen) chemisorbed on a variety of surfaces; and from hydrocarbons and other organic molecules similarly adsorbed on metals or on oxides. The final brief chapter in this section discusses a number of general spectroscopic topics concerned with chemisorption and catalysis.

The second part of the book is concerned largely with infra-red spectra from physically adsorbed molecules on oxide surfaces (particularly with respect to interactions with surface hydroxyl groups) and on related adsorbents such as clay minerals and zeolites. For physical adsorption the interpretation of the spectra is more straightforward, for this leads only to perturbations of spectra familiar in other phases. Infra-red spectroscopy has contributed greatly and directly to an understanding of the nature of physical adsorption on such surfaces. A valuable feature of this part of the book consists of contributions from two Russian authors, Professor Kiselev and Dr Lygin, in the form of separate chapters or supplements to those written by Dr Little. Much of the pioneering spectroscopic work, particularly on physical adsorption, was carried out by the late Academician Terenin and his colleagues in Leningrad and in a number of cases this work is only available in Russian language journals. It is therefore particularly valuable that these and later substantial contributions have been authoritatively reviewed by the Russian co-authors.

In summary, this book provides a welcome, comprehensive and fairly critical review of the whole field of infra-red spectroscopic investigations of adsorbed molecules; the only notable omission noticed concerned a number of publications from the Italian school under Bonino and Fabbri. It is a very valuable reference book for specialists in this field, and should be of interest and use to many other surface chemists.

N. SHEPPARD

## TOPOLOGICAL TEXT

### Elementary Topology

A Combinatorial and Algebraic Approach. By Donald W. Blackett. (Academic Press Textbooks in Mathematics.) Pp. ix + 224. (New York: Academic Press, Inc.; London: Academic Press, Inc. (London), Ltd., 1967.) 76s.

THIS is one of a number of attractive textbooks beginning to appear on the market which are designed to foster the undergraduate student's interest in algebraic (that is non-point-set) topology without making heavy demands on

his technique. Its presentation, which is informal and incorporates many beautiful pictures, gives one the feeling "this isn't going to hurt". Unfortunately, many readers will suffer agony before reading the last chapter. Much of this is because of the sheer difficulty of the subject—each problem has to be tackled with bare hands and technical details have to be glossed over, with consequent loss of clarity. There does seem to be, however, a general lack of motivation; for example, in the chapter on network theory, the reader is led through pages of difficult calculations involving the boundary operator, without being previously told what they are for. There are seven chapters; in the first two, compact surfaces are classified by triangulation and in the third there are applications to Riemann surfaces. Winding number, the degree of a map, the Brower fixed-point theorem and the Borsuk-Ulam theorem for surfaces, with applications to complex analysis, occupy chapter four. The fifth treats vector fields and their singularities. The sixth and seventh, respectively, cover network theory and some topology of 3-manifolds. There are about three pages of exercises at the end of each chapter. The book would certainly be of value to anyone teaching topology at this level.

C. B. RAYNER

## TEXT FOR GEODESISTS

### Physical Geodesy

By Weikko A. Heiskanen and Helmut Moritz. (A Series of Books in Geology, edited by Gilluly and Woodford.) Pp. vi + 364. (San Francisco and London: W. H. Freeman and Company, 1967.) 110s.

NINE years ago one of the authors of this book, Professor Heiskanen, and the late Professor Vening Meinesz wrote *The Earth and its Gravity Field* which was widely acclaimed. Until then the application of measurements of the intensity of gravity to the study of geodesy, and the determination of the Figure of the Earth, was largely based on the well known theorem of Stokes, first published in 1849. The great disadvantage of this approach is that gravity anomalies have to be reduced to a co-geoid which is a bounding equipotential surface before the theorem can be used, necessitating assumptions as to the density of the Earth's topography which has to be computationally removed. In 1945 Molodensky proposed a new approach which used ground level gravity anomalies without further reduction; in the last ten years or so many scientists have followed and further developed such methods. Consequently Heiskanen and Moritz have written a book which is completely new, rather than a revision of *The Earth and its Gravity Field*. The major difference between the new book and the old is that the new one describes this modern theory and, as a consequence, there is no space for any of the chapters on the geophysical aspects of gravity which formed a large part of the old book.

The first five chapters cover the material for a basic course in physical geodesy. The first chapter is entitled "Fundamentals of Potential Theory". It is complete and well explained although many long derivations of formulae are omitted and the reader is referred to standard textbooks. The second chapter is entitled "The Gravity Field of the Earth"; this again is well presented and includes full discussions of the generalized Stokes formula and the determination of the physical constants of the Earth. The third chapter, "Gravimetric Methods", describes the various conventional forms of reduction and the practical determination of the geoid, including the theory and use of isostasy.

The fourth and fifth chapters, "Heights above Sea Level" and "Astro-geodetic Methods", formulate the reductions necessary to height and astronomical measurements to bring them to the geoid or ellipsoid. Although there are paragraphs on accuracy and the effect of gravity and

density errors on height, there appears to be nowhere in the fourth chapter a reasoned statement as to when normal or theoretical gravity may be used instead of measured gravity without significant loss of accuracy. The authors, however, state in their preface that the book "is intended to be theoretical in the sense in which the word is used in the term 'theoretical physics'", so they are being consistent. A corollary of this is that there is no chapter on instruments or the measurement of gravity.

The remaining four chapters present more specialized and advanced topics. The sixth chapter gives formulae for the "Gravity Field outside the Earth". The seventh chapter gives a short discussion on "Statistical Methods in Physical Geodesy" which are in wide use today, while the eighth chapter is entitled "Modern Methods for Determining the Figure of the Earth". If criticism has to be made, it is that these last two chapters are too short; for instance de Graaf-Hunter's "Model Earth" is merely referred to in one line. The ninth chapter devotes twenty-six pages to "Celestial Methods", including the use of the Moon as well as artificial Earth satellites; it thus necessarily gives but an outline of the subject matter.

Attention must be drawn to one important feature: the concept of the geoid is fully maintained, not rejected as obsolete, and geometrical interpretations are given of all modern methods, adding much to their understanding and appreciation. The authors thus show that the supposed dichotomy between the new thinking and the old is not nearly as great as some would imply, and a full reconciliation of the two approaches is made.

As is inevitably the case today, the most up to date information on all the topics discussed in the book can only be found in many and widely different journals or university publications, not all of which are readily available to the average geodesist. Almost every geodetic measurement depends in a fundamental way on the Earth's gravity field, and so the authors have performed a signal service to geodesy in collating such information in one volume, and presenting it in a logical form and sequence which is readily understandable. They are to be congratulated not only on producing a much-needed book which every geodesist should buy, but also on writing in such impeccable English, which is the native tongue of neither.

It remains to add that each chapter has a full list of references at the end, and that there is a detailed list of contents and a good index. The book is well produced and the numerous diagrams are very clear; this and the apparent lack of misprints show a happy co-operation between the authors and the publisher. A. R. ROBBINS

## POLYMERS RE-ISSUED

### High-Temperature Polymers

Edited by Charles L. Segal. Pp. viii + 197. (London: Edward Arnold (Publishers), Ltd.; New York: Marcel Dekker, Inc., 1967.) 70s. net.

IN 1966 Marcel Dekker, Inc., launched the *Journal of Macromolecular Chemistry*. By the time the second or third issues of the first volume appeared plans must have been advanced to replace this journal in 1967 by the *Journal of Macromolecular Science* published in four sections. In Britain the total subscription to this journal is \$154 and many libraries may await an assessment of its quality before ordering, for this is more than four times the price of the pilot journal of 1966. Part A of the *Journal of Macromolecular Science*, devoted to chemistry, is the direct successor of the 1966 journal. The first two issues consist of papers presented at symposia, one on high temperature polymers and one on polyaldehydes. Subsequent issues of Part A, Volume 1, contain contributed research papers.

The two symposium issues have now been re-issued separately as hard-backed volumes. The first is being reviewed here. Because all these publishing activities are of recent origin I have felt it advisable to draw the attention of readers to them. Those who receive or intend to order the new journal may not wish to duplicate material and expenditure by purchasing some issues again in hard-backed form.

This symposium on high temperature polymers was held by the American Chemical Society at a Western Regional Meeting in November 1965. It contains eight papers, an editor's introduction and one summary paper. About half of the papers take a general approach to their subjects, particularly those of Marvel and Van Wazer, so that the lapse of time since they were given does not detract from their interest. They show that, despite much work and progress, a great deal more is urgently needed in this challenging field. Other papers are reports on work in progress to which fresh results have since been added.

It is doubtful whether such a regional one-day symposium justifies this double publication, but if it is to be done it should be done in such a way that the book version has, in isolation, a lasting value. In his preface the editor speaks of the extensive discussion which followed the papers, but none of this is recorded in the book. A number of serious misprints occur which should have been corrected in such a re-issue; examples are the omission of scale numbers from thermograms and an error in equation (1) of Van Wazer's article. As a collection, the papers do not represent a deliberately systematic coverage of high temperature polymers. The addition of several more specially commissioned general articles and an index would have greatly enhanced the scientific value of this publication as a separate book. PATRICK MEARES

## HOW PROTEINS ARE MADE

### Techniques in Protein Biosynthesis

Vol. 1. Edited by P. N. Campbell and J. R. Sargent. Pp. xii+336. (London: Academic Press, Inc. (London), Ltd.; New York: Academic Press, Inc., 1967.) 80s.; \$15.

### Regulation of Nucleic Acid and Protein Biosynthesis

Edited by V. V. Koningsberger and L. Bosch. (B.B.A. Library, Vol. 10.) Pp 412. (Amsterdam, London and New York: Elsevier Publishing Company, 1967.) 140s.

THE first of these two books does not, as the title might suggest, contain precise details of techniques used to investigate protein biosynthesis, but contains a series of reviews with more or less emphasis on practical procedures. The first chapter, written by the editors, is an excellent summary of the experiments that have led to our present knowledge of the structure and biosynthesis of proteins. The second and third chapters, by A. von der Decken and J. R. Sargent, respectively, review experiments on protein biosynthesis in mammals. The fourth chapter, by M. S. Bretscher and O. W. Jones, reviews experiments that have elucidated the genetic code. Practical procedures are emphasized in the second, third and fourth chapters. K. S. Kirby, in the next chapter, after paying due attention to the importance of ribonucleic acids in protein biosynthesis, proceeds to present a valuable summary of methods of isolating RNA. The volume ends with thirteen pages of odd techniques with practical details. The exact purpose of this book is difficult to grasp, for no biochemist wants to make a routine procedure of solving the genetic code, or elucidating the mechanism of protein biosynthesis; and even if he did, the practical details presented would be inadequate. Nevertheless, articles such as these are essential for teaching advanced biochemistry, and it is lucky that leading research workers are willing to write them. I can

think of no better article on protein biosynthesis for a student than the first chapter of this book.

The second book contains thirty-three papers presented at a symposium in the Netherlands in June 1966, together with a summary of the meeting by H. Chantrenne. The authors include many stars from outside the Netherlands such as A. Kornberg, S. Ochoa, S. Spiegelman, F. Jacob, F. Lipmann, J. Bonner, J. Brachet and C. E. Sekeris. The book contains what were in mid-1966 the latest experimental results and ideas of most of the principal workers in nucleic acid and protein biosynthesis and their regulation. Progress in this area is not so rapid as it was a few years ago, and the volume will be invaluable reading for research workers for a year or so. The first of four sections is entitled "DNA Synthesis and its Regulation". It contains papers on the ultrastructure of the animal chromosome, and the biosynthesis and repair of DNA. The second section, "RNA Synthesis", is largely concerned with the mechanism of action of enzymes that synthesize RNA. The third section, "Protein Synthesis", contains papers on the mechanism of incorporation of amino-acids into polypeptides. The fourth section, "Regulation of RNA and Protein Synthesis", is the largest. Its topics include histones and other possible gene regulators; the regulation of protein synthesis in bacteria, yeast, liver and enucleate cells; and the effect of ecdysone on RNA and protein metabolism. J. M. BARRY

## NUTRITION AFTER BIRTH

### Utilization of Nutrients during Postnatal Development

By P. Hahn and O. Koldovsky. (International Series of Monographs in Pure and Applied Biology. Division: Zoology, Vol. 33.) Pp. xi+177. (Oxford, London and New York: Pergamon Press, Ltd., 1966.) 50s. net.

NEONATAL physiology and medicine must be reckoned among the growing points of knowledge at the moment, and some time ago the Czechoslovakian Academy of Sciences had the foresight to recognize this and to establish a special department of developmental physiology, which has now justly earned a reputation in many parts of the world. Had it not been for language difficulties, moreover, and the all too common parochial attitude to international literature, its fame might have been even greater.

The authors of this book have done the English speaking world a service by summarizing certain aspects of the work on developmental physiology, based particularly on studies made on the rat and to a lesser extent on man. They have, naturally, drawn largely, but by no means entirely, on their own experiences, and this is probably the most valuable thing they could have done, for they have freer access to the literature of Eastern Europe and Russia than most of the rest of us.

The authors have been concerned mainly with the nutritional aspects of development. This has involved a review of the way the nutrients are obtained, the amounts that have to be obtained and the way they are expended. In connexion with this last topic the authors rightly felt it necessary to consider thermal regulation in the newborn and its cost in terms of food. This was a service in itself, for it led them to review much of the earlier fundamental Czech and Hungarian literature on this subject. The authors' own experiments have largely been concerned with weaning rats earlier or later than the normal practice, and the part played by carbohydrate and fat in the normal metabolic sequences of development. This is the main theme also in the chapter on the human foetus and newborn which has been contributed by V. Melichar and M. Novak. Protein foods and protein metabolism have been relatively neglected, and the role of the gut in absorbing unchanged proteins and antibodies has scarcely been mentioned. This is a pity, for this is one of the most

fascinating aspects of developmental physiology and a very important one for survival in some species. There are 600 references, which, in a book of this length, gives cause for reflexion.

The rat has been a very productive animal in this field, for it is normally born in an immature state. Thus, many developmental changes, which cease long before birth in a sheep or a guinea-pig, take place after birth in the rat, and are consequently open to similar experimental investigation. The authors therefore did well to choose it and, short of marsupials, which have so far scarcely been studied from this point of view, they could hardly have chosen better. Perhaps the authors, with all their experience and access to a literature which is difficult for the rest of us to enjoy, could have made the book a little less factual and objective, and given us more of their own judgments and criticism. This, however, is becoming a more and more difficult thing to do, and the more literature one sets out to quote the more difficult it tends to become.

The ability to write books of this kind and to sponsor small conferences on subjects of international interest are two of the privileges of Czechoslovakian scientists, and they are making the most of them.

R. A. McCANCE

## CEREBROSPINAL TREATISE

### Physiology of the Cerebrospinal Fluid

By Hugh Davson. Pp. vii + 445. (London: J. and A. Churchill, Ltd., 1967.) 84s.

It is rare to find a book which can be said to be faultless, but it is almost true of Dr Davson's book, which has been eagerly awaited and now is found to fulfil all expectations. The only fault I could find was a transposition of figures 46 and 47, on pages 76 and 77.

Although the present work is based on Dr Davson's original book *The Physiology of the Ocular and Cerebrospinal Fluids* published in 1956, it shows so few traces of the old that it can justly be regarded as a new book devoted to the cerebrospinal fluid. If this should seem too narrow a field, a few minutes looking through the pages will disprove it. Pharmacology, electron microscopy, brain metabolism, renal and respiratory physiology are all included, so that the cerebrospinal fluid becomes integrated with other body fluids and processes in a concise and sparkling style.

Although designated as an introductory account of the physiology of the cerebrospinal fluid, it is very much more and must surely be regarded as the authoritative text. The author is world renowned for his experimental work on the cerebrospinal fluid and this experience is evident in his lucid explanations and critical analyses of the vast mass of experimental work on this subject. The production, composition, pressure and absorption of cerebrospinal fluid naturally occupy a good deal of the text, most of it referring to experimental work. There are, however, intriguing references to clinical material, largely gathered into the last three chapters, concerned with blood brain barrier, acid base characteristics of respiration and the cerebrospinal fluid pressure. The illustrations are clear and well placed with regard to the text, while there are more than 1,000 references from a wide range of sources.

Dr Davson's book arrives opportunely at a time when a great deal of interest is being focused on the cerebrospinal fluid, especially among clinicians, who will find in this work the answers to many of their queries and, perhaps even more important, will find that a large number of questions are raised. Dr Davson is to be congratulated on a work of scholarship and this book can be recommended unreservedly.

EDWARD HITCHCOCK

## OBITUARIES

### Professor J. A. Chalmers

JOHN ALAN CHALMERS, who died on March 14, was born in 1904 within the sound of Bow Bells and was a Foundation Scholar of Highgate School, from which he won an open scholarship in natural sciences to Queen's College, Cambridge. He went up to Cambridge in 1923 and in the course of a distinguished undergraduate career gained first class honours in parts one and two of the natural sciences tripos. He then did research in radioactivity under Rutherford, but left in 1928 to take up a lectureship in physics at the University of Durham, where he spent the remaining thirty-eight years of his academic life. In 1932 Chalmers took up the study of atmospheric electricity, a subject which became his dominant research interest and to which he and his research students made many contributions. Those who knew Chalmers best can see how perfectly his chosen research fitted his love of the open air and his intense interest in natural phenomena. Chalmers' lively mind ranged over a wide field—point discharge phenomena, precipitation electricity, atmospheric ionization, and the Earth's electric field. Although at first he enjoyed only limited resources of money and equipment, by his persistence and enthusiasm he gradually built up a large research group with well equipped field laboratories at the department of physics in Durham and at the university observatory. With Pasquill he measured the electrical charges carried by raindrops, and with Whipple he worked out a theory of the capture of ions by falling drops, a theory later extended to ice crystals. With Hutchinson he investigated the mechanism of the charging of drops and ice crystals. He worked extensively on natural objects and, for example, demonstrated the part played by living trees in transferring electrical charge from clouds to the Earth. He also investigated the electrical field conditions of artificial points on masts and tethered balloons in various meteorological conditions. Some of the problems chosen were not perhaps the most fruitful because of their inherent complexity and the vagaries of the weather, but Chalmers made them challenging and stimulating, and as his resources increased he developed more powerful instrumentation. His more recent work was concerned with a theoretical analysis of the electrode effect at the Earth's surface and the identification of an unexpected negative potential gradient in conditions of mist and fog as the secondary product of corona discharges from distant electrical power transmission lines. His researches were not confined to atmospheric electricity; early in his career he wrote a series of papers on contact potential, and throughout his life he worked on problems in classical electricity and magnetism. He also gave vigorous support to the M.K.S. system of units. His output of papers was prolific, and he published about a hundred papers and two books on atmospheric electricity, the second of which is probably the best treatment of the subject in English.

Chalmers served Durham well in teaching and administration. He was well known to generations of students and his feats of memory were legendary. His detailed knowledge of degree regulations and his work on the modernization of first degree courses made him an almost automatic choice for dean of the faculty of science in 1965, an office which he held until his death. The university recognized his many contributions to its work by electing him to a personal chair.

In the wider life of the city and county, Chalmers' name was synonymous with scouting. He devoted all his spare time to this work, and at weekends and in vacations could be seen leaving Durham for a camping or climbing holiday with his touring car, or in later years his van, bulging with boys.

G. D. ROCHESTER  
W. C. A. HUTCHINSON

## University News :

### Birmingham

PROFESSOR R. B. HUNTER, at present professor of materia medica in the University of St. Andrews, has been appointed vice-chancellor and principal of the university.

### Bradford

MR D. P. HOWSON, at present senior lecturer in the Department of Electronic and Electrical Engineering, University of Birmingham, has been appointed to the additional chair of electrical engineering, and Dr J. B. Helliwell, at present reader in gas dynamics in the University of Strathclyde, has been appointed to the chair of mathematics.

### Cambridge

DR H. LEHMANN, university biochemist to the Cambridge United Hospitals, has been appointed to the chair of clinical biochemistry.

### Leeds

A NEW Division of Virology, under the headship of Dr Jaroslaw Czekalowski and within the Department of Bacteriology, has been created in the university.

### London

THE following appointments have been made: Dr R. F. L. Logan, at present reader in social medicine in the University of Manchester, to the chair of organization of medical care at the London School of Hygiene and Tropical Medicine; Professor W. R. Niblett, at present dean of the Institute of Education, to the newly established chair of higher education tenable at the institute; Dr. A. J. Rutter, reader in ecology in Imperial College, to the chair of botany tenable at that college. The title of professor of chemistry has been conferred on Dr C. A. Vernon, in respect of his post at University College.

### Sussex

PROFESSOR J. C. WEST, at present dean of the School of Applied Sciences, has been appointed as pro-vice-chancellor of the university for a period of two years from August 1; Professor T. B. Bottomore, at present head of the Department of Political Science, Sociology and Anthropology in the Simon Fraser University, British Columbia, has been appointed to the chair of sociology, and Mr. A. Kirk, at present director of the Computer Laboratory in the University of Liverpool, has been appointed director of the Computing Centre.

## Appointments

THE following appointments have been made by the Medical Research Council to its three advisory research boards: *Biological Research Board*, Professor A. S. V. Burgen of the Department of Pharmacology, University of Cambridge; Professor K. Burton of the Department of Biochemistry, University of Newcastle upon Tyne; Professor P. M. B. Walker of the Department of Zoology, University of Edinburgh. Professor J. L. Gowans of the Sir William Dunn School of Pathology, Oxford, already a member of the board, will succeed Professor W. D. M. Paton as chairman. *Clinical Research Board*, Professor A. W. Kay, regius professor of surgery in the University of Glasgow. *Tropical Medicine Research Board*, Professor W. Melville Arnott of the Department of Medicine, University of Birmingham; Dr D. J. Lewis of the British Museum (Natural History).

PROFESSOR H. R. HEWER, professor of zoology in Imperial College, has been appointed chairman of the new Farm Animal Welfare Advisory Committee, which has been set up to advise the Ministry of Agriculture, Fisheries and Food and the Scottish Office on matters involving the welfare of farm animals kept under intensive husbandry systems.

MR J. A. H. PAFFETT, at present holder of the chair of naval architecture at the Royal Naval College, Greenwich, has been appointed superintendent of the Ship Division of the Ministry of Technology's National Physical Laboratory. He is succeeding Mr A. Silverleaf, who is now deputy director (C) at the National Physical Laboratory.

## Announcements

THE *Royal Society Leverhulme Visiting Professorships* have been awarded as follows: Professor S. Devons, professor of physics and chairman of the Department of Physics at Columbia University, to visit the University of Andhra, Waltair; Professor D. Whitteridge, professor of physiology and head of the Department of Physiology at the University of Edinburgh, to visit the Vallabhbhai Patel Chest Institute, University of Delhi; Professor W. Williams, professor of plant science and head of the Department of Plant Science in the University of Newcastle upon Tyne, to visit the Agricultural College of Prague, the Faculty of Natural Science of the Charles University and the Institute of Experimental Botany of the Czechoslovak Academy of Sciences. The *Royal Society Visiting Professorships* have been awarded to Professor F. C. Champion, professor of physics at King's College in the University of London, to visit the University of Malaya, Kuala Lumpur, and Professor N. Tinbergen, professor of animal behaviour at the University of Oxford, to visit the University of East Africa.

DR S. H. SHAW, adviser to the Ministry of Overseas Development and in charge of the Overseas Division of the Institute of Geological Sciences, has been elected president of the Institution of Mining and Metallurgy for the session 1968-69.

THE Institution of Civil Engineers has awarded the *Telford Gold Medal* jointly to J. K. Anderson, J. A. K. Hamilton, W. Henderson, J. S. McNeil, Sir Gilbert Roberts and H. Shirley-Smith for their paper, "The Forth Road Bridge". The *James Watt Medal* has been awarded to A. R. Wilkinson; and the *George Stephenson Medal* to P. A. Scott.

THE Colworth Medal, which has been donated by the Unilever Research Laboratory, is awarded annually by the Biochemical Society to the most promising young British biochemist. Nominations are invited for the award of this medal for the year 1967, and further information can be obtained from the Honorary Secretary, The Biochemical Society, 7 Warwick Court, London, WC1.

# CORRESPONDENCE

## Projects for Schools

SIR,—Nigel Hawkes reports (*Nature*, 215, 122; 1967) that a boy at a certain British school carried out on mice experiments which, so far as a reader can judge, ought not to be done without a Home Office licence and Certificate A. Whether little or much discomfort was caused by the changes of temperature mentioned by Mr Hawkes, the matter is serious because it could be the thin end of the wedge. In America children are encouraged to repeat even severe experiments on animals, and British publishers have, to my knowledge, refused the British rights of at least three American books telling amateurs how to amuse themselves in this way. British scientists have a highly responsible tradition in such matters but there is strong American pressure on European education, and vigilance seems to be called for.

Yours faithfully,

C. W. HUME

The Athenaeum,  
Pall Mall, S.W.1.

## APPOINTMENTS VACANT

APPLICATIONS are invited for the following appointments on or before the dates mentioned:

**PRINCIPAL SCIENTIFIC OFFICER** (with a good honours degree, preferably in physics or in mathematics or engineering, and experienced in the administration of scientific work) to take charge of the SCIENTIFIC ADMINISTRATION GROUP at the Rutherford Laboratory which is the leading research establishment in elementary particle physics in the U.K.—Mr. G. N. Pickles, The Rutherford Laboratory, Chilton, Didcot, Berkshire, quoting Ref. 409/34 (August 17).

**RESEARCH ASSISTANT** to Professor D. J. Carr, Head of the DEPARTMENT OF BOTANY—The Secretary, Department of Botany, Queen's University, David Keir Building, Belfast 9, Northern Ireland (August 19).

**RESEARCH FELLOW** (with a Ph.D. degree and experience of analytical geochemistry) in the DEPARTMENT OF GEOLOGY to carry out analyses of carboniferous sedimentary rocks—The Registrar, University College of Swansea, Singleton Park, Swansea (August 19).

**TUTOR LIBRARIAN** (graduate with library qualifications and experience) in the Institute of Education—The Registrar, The University, Keele, Staffordshire (August 19).

**PRINCIPAL** (national of the United Kingdom or the Republic of Ireland, science graduate with wide industrial and technical college experience preferably including responsibility for laboratory technician courses, and preferably a knowledge of Portuguese) of the SCHOOL OF MEDICAL LABORATORY TECHNOLOGY, Federal University of Minas Gerais, Brazil—The Council for Technical Education and Training for Overseas Countries, Eland House, Stag Place, London, S.W.1, quoting Ref. TET/BRZ/12 (August 21).

**PRINCIPAL** (national of the United Kingdom or the Republic of Ireland, with a good degree in science or engineering and wide experience in technical education) of the NORTHERN TECHNICAL COLLEGE, Zambia—The Council for Technical Education and Training for Overseas Countries, Eland House, Stag Place, London, S.W.1, quoting Ref. TET/NDZ/12 (6) (August 21).

**COX CHAIR OF ANATOMY**—The Secretary, The University, Dundee, Scotland (August 26).

**RADIATION OFFICER** (preferably with a knowledge of radiation protection and electronics) in the DEPARTMENT OF PHYSICS—The Registrar, The University of Manchester, Manchester, 13, quoting Ref. 120/67/Na (August 26).

**RESEARCH FELLOW** (with computer programming experience, an interest in information retrieval, and preferably some knowledge of statistical methods) in MEDICAL DATA PROCESSING—The Registrar, The University, Keele, Staffordshire (August 26).

**LECTURER or ASSISTANT LECTURER in PSYCHOLOGY**—The Secretary, The University, Dundee, Scotland (August 31).

**LECTURER** (preferably with previous experience in model building for computer control) in CONTROL ENGINEERING—The Registrar, University of Bradford, Bradford, quoting Ref. L/COE/5/X (August 31).

**LECTURER** (with wide experience of general medicine, but previous experience in rheumatology not essential) in RHEUMATOLOGY—The Registrar, The University, Manchester 13, quoting Ref. 128/67 (August 31).

**LECTURERS/SENIOR LECTURERS in PURE MATHEMATICS** at the University of Sydney, Australia—The Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (Australia and London, August 31).

**ASSISTANT LECTURER** (with the M.B. or Ph.D. degree in the physiological sciences and preferably experience in teaching and research) in PHYSIOLOGY—Head of the Department of Physiology, University College, Merrion Street, Dublin 2, Republic of Ireland (September 1).

**ENTOMOLOGIST, SCIENTIFIC OFFICER** (with a first- or upper second-class honours degree and preferably postgraduate experience in entomology) to study resistance to aphids in sugar beet and other crop plants—The Secretary, Plant Breeding Institute, Maris Lane, Trumpington, Cambridge (September 1).

**LECTURER** (with basic training in bacteriology and pathology) in the DEPARTMENT OF BACTERIOLOGY—The Secretary, The London Hospital Medical College (University of London), Turner Street, London, E.1 (September 1).

**SCIENTIFIC OFFICER** (with a good degree and an interest in the developmental physiology of plants and in genetics) in the CYTOGENETICS SECTION to work on the developmental aspects of the present programme for the cytogenetic analysis of wheat—The Secretary, Plant Breeding Institute, Trumpington, Cambridge (September 1).

**LECTURER or ASSISTANT LECTURER in the COMPUTING LABORATORY** to give lectures on programming languages and techniques to undergraduate and graduate students and to advise computer users on the preparation of programmes—The Secretary, The University, Dundee, Scotland (September 2).

**LECTURER or ASSISTANT LECTURER in PHYSIOLOGY**—The Registrar, The University, Sheffield (September 2).

**LECTURER** (registered medical practitioner and preferably with some experience in hospital laboratory work, particularly in a biochemical department) in the DEPARTMENT OF CLINICAL CHEMISTRY—The Secretary, University of Edinburgh, Old College, South Bridge, Edinburgh (September 2).

**RESEARCH FELLOW** (with a Ph.D. or equivalent) in PHYTOCHEMISTRY in the Postgraduate School of Studies in Pharmacy—The Registrar, University of Bradford, Bradford 7, quoting Ref. P/R/F (S)/1/E (September 4).

**SENIOR LECTURERS (2), and a LECTURER in the DEPARTMENT OF PHYSICS**, University of Ife, Nigeria—The Inter-University Council, 33 Bedford Place, London, W.C.1 (September 4).

**LECTURER or ASSISTANT LECTURER in BIOLOGY (Senior College); and LECTURERS (2) in BIOLOGY (Junior College)** at the Royal University of Malta—The Inter-University Council, 33 Bedford Place, London, W.C.1 (September 6).

**ASSOCIATE PROFESSOR in the DEPARTMENT OF PATHOLOGY; and a LECTURER/SENIOR LECTURER in PATHOLOGY**, University of Sydney, Australia—The Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (Australia and London, September 8).

**LECTURER in the DEPARTMENT OF SURGICAL SCIENCE**—The Secretary, University of Edinburgh, Old College, South Bridge, Edinburgh (September 9).

**CHAIR OF SURGERY at Monash University**—The Secretary-General, Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1; or the Academic Registrar, Monash University, Clayton, Victoria, Australia (Australia and London, September 11).

**CHAIR OF GEOGRAPHY at the proposed UNIVERSITY OF DUNDEE**—The Secretary, Queen's College, Dundee, Scotland (September 15).

**LECTURER** (with experience in industry or chemical engineering) in APPLIED CHEMISTRY at the University of Otago, Dunedin, New Zealand—The

Secretary-General, Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (New Zealand and London, September 15).

**RESEARCH FELLOW** (with some experience in the application of computers to structural analysis and preferably completed work for a higher degree) in STRUCTURAL COMPUTING to work on the application of digital computer methods to the optimum design of multi-storey frames—The Registrar, The University, Manchester 13 (September 15).

**LECTURER in MICROBIOLOGY (non-clinical)**—The Secretary, The Queen's University, Belfast, Northern Ireland (September 30).

**LECTURER** (with medical qualifications and training in pharmacology) in PHARMACOLOGY in the DEPARTMENT OF MATERIA MEDICA AND THERAPEUTICS—The Secretary, The University, Aberdeen (September 30).

**READER** (preferably with interests in the fields of numerical mathematics or statistics) in MATHEMATICS; and a **SENIOR LECTURER or LECTURER** (with a higher degree in chemical engineering or a related discipline coupled with academic research or professional engineering experience; or a good honours degree and some years industrial experience, and preferably an interest in fluid mechanics or heat and mass transfer) in CHEMICAL ENGINEERING at the University of Canterbury, Christchurch, New Zealand—The Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (September 30).

**TEMPORARY RESEARCH ASSISTANT** (with a good honours degree in botany and some postgraduate training or research experience) in the DEPARTMENT of CELL BIOLOGY to work on plant cell hybridization—The Secretary, John Innes Institute, Colney Lane, Norwich, NOR 70F (September 30).

**TAXONOMIC MYCOLOGISTS** (with a good honours degree with postgraduate experience of the systematics of micro-fungi) in the Commonwealth Mycological Institute's identification service—The Secretary, Commonwealth Agricultural Bureaux, Farnham House, Farnham Royal, Bucks (October 15).

**HEAD OF THE STATISTICS DEPARTMENT**—The Secretary, Rothamsted Experimental Station, Harpenden, Herts (October 21).

**LECTURER in the SCHOOL OF CHEMICAL ENGINEERING**, University of New South Wales—The Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (Australia and London, October 30).

**ASSISTANT EXPERIMENTAL OFFICER** (with a degree or equivalent in horticulture, agricultural botany or a biological subject) for field and laboratory work with pesticides and soil organisms at the Field Station—Dr N. G. Hague, Imperial College Field Station, Ashurst Lodge, Sunninghill, Ascot, Berks.

**DIRECTOR (M.D. or Ph.D. with current knowledge and experience in biomedical engineering)** of the BIOMEDICAL ENGINEERING DEPARTMENT—The Executive Director, Ottawa Civic Hospital, 1053 Carling Avenue, Ottawa 3, Ontario, Canada.

**GRADUATE RESEARCH ASSISTANT in the DEPARTMENT OF CHEMICAL PATHOLOGY** to work on protein metabolism in brain by tracer techniques—The Secretary, Institute of Neurology (University of London), The National Hospital, Queen Square, London, W.C.1.

**RESEARCH ASSISTANT (biochemist or veterinary pathologist)** (preferably with postgraduate research experience and/or a higher degree, experience in immunological techniques, protein and enzyme chemistry and/or tumour transplantation in pure strain animals) in the IMMUNOLOGY CANCER RESEARCH UNIT—The Registrar, The University, Liverpool, 3, quoting Ref. RV/100/N.

**RESEARCH FELLOW or RESEARCH ASSISTANT** (physical chemist or biophysicist, preferably with postgraduate research experience and/or a higher degree) in the IMMUNOLOGY CANCER RESEARCH UNIT—The Registrar, The University, Liverpool, 3, quoting Ref. RV/99/N.

**RESEARCH SCIENTIST** (with a Ph.D. degree in science or postgraduate research experience of an equivalent standard and duration, preferably in the field of ecology, supported by satisfactory evidence of research ability, and preferably experience with animal ectoparasites or disease vectors) in the DIVISION OF WILDLIFE RESEARCH, Commonwealth Scientific and Industrial Research Organization, Canberra, to undertake a study of the epidemiology of myxomatosis, with a view to assessing the present status of the disease in various geographic regions in Eastern Australia—Chief Scientific Liaison Officer, Australian Scientific Liaison Office, Africa House, Kingsway, London, W.C.2, quoting Appointment No. 560/226.

**SENIOR LECTURER/LECTURER** (with a higher degree in philosophy, or both a degree in philosophy and a degree in a subject related to their special interest, for example, mathematics, physics, anthropology) in PHILOSOPHY at the University of Queensland, Australia—The Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1.

**S.R.C. RESEARCH STUDENT in the DEPARTMENT OF CHEMISTRY** for work on the inhibition of the combustion of polymers—Professor C. F. Cullis, Department of Chemistry, The City University, St. John Street, London, E.C.1, quoting Ref. 42 CH.

**TECHNICIAN** (with previous experience of assembling electronic equipment) in the DEPARTMENT OF MACHINE INTELLIGENCE AND PERCEPTION for duties which will include assisting with the design, construction and maintenance of experimental devices for use with the Department's Elliott 4100 computer, and the maintenance of off-line electro-mechanical equipment—The Secretary, University of Edinburgh, Old College, South Bridge, Edinburgh, 8.

## HOW TO BUY NATURE

Volumes start in January, April, July and October, but subscriptions may begin with any issue.

The direct postal price per subscription for one or two copies of NATURE each week is:

**\*12 MONTHS** (52 issues and 4 indexes)

Great Britain and Eire.....**£14.0.0** each  
 United States of America.....(by air freight).....**\$44** each  
 Canada.....(by air freight).....**\$47.80** each  
 Elsewhere overseas by surface mail.....**£13.15.0** each

(Charge for delivery by air mail on application)

\*Shorter periods *pro rata*. (Minimum three months.)

### MULTIPLE SUBSCRIPTIONS

For subscribers who take more than two copies of NATURE each week these reduced annual rates are offered:

**12 MONTHS** (52 issues and 4 indexes)

Number of Copies	G.B. & Eire	U.S.A. (by air freight)	Canada (by air freight)	Elsewhere (surface mail)
3-5	<b>Each £13.10.0</b>	<b>Each \$42</b>	<b>Each \$46.00</b>	<b>Each £13.10.0</b>
6-11	<b>£12.15.0</b>	<b>\$40</b>	<b>\$43.60</b>	<b>£12.15.0</b>
12 or more	<b>£12.0.0</b>	<b>\$38</b>	<b>\$41.70</b>	<b>£12.0.0</b>

Multiple subscriptions must run concurrently. Every copy will be posted separately, and for speed of delivery each subscription can be addressed to a different individual, or department at the same address. (ZIP essential for U.S.A.)

## GAS CHROMATOGRAPHY AND OTHER INTEGRATION APPLICATIONS

Kent Chromalog

## GAS CHROMATOGRAPHY INFRA-RED ANALYSIS MASS SPECTROMETRY COULOMETRIC ANALYSIS LABORATORY AUTOMATED ANALYSIS

Kent Scientific Recorder

# Versatile Kent Instruments for the laboratory

**KENT CHROMALOG**, completely self-contained and portable solid-state integration system that evaluates chromatograms accurately, immediately and automatically by providing direct digital print-out of peak areas. The Chromalog renders obsolete all tedious manual methods of integration and gives far more reliable results. Already specified as standard equipment for a wide variety of analytical applications, the Chromalog is used extensively in conjunction with the Scientific Recorder.

**KENT SCIENTIFIC RECORDER**, a single-point millivolt recorder for measurement of any variable that can be expressed in terms of voltage. The Scientific Recorder is a special development of the internationally familiar Mark 3 range and is designed to meet the particular requirements of research, development

and academic laboratories. A 36-range plug-in card is available to complement the many built-in features of this versatile instrument.

Test our service—telephone Mr. G. H. Sharp, Luton 21151, or write for details by return.

### ***Classified Advertisements***

Semi-displayed £4 16s. per single column inch. Minimum £2, each additional 1/12th of an inch 8s. Full page £132. Half page across £66. Colour (orange) £15 extra. 1s. is charged for the re-direction of replies to advertisements with a box number.

ADVERTISEMENTS SHOULD BE ADDRESSED TO: T. G. Scott and Son, Limited, 1 Clement's Inn, Strand, London, W.C.2. Telephone: 01-405 4743. Telegrams: Textualist, London, W.C.2.

### **APPOINTMENTS VACANT**

#### **UNIVERSITY OF SINGAPORE**

Applications are invited for (a) Lectureship or (b) Assistant Lectureship in Department of Anatomy. Salary scales (a) £1,456 to £2,184 per annum; (b) £1,288 to £1,400 per annum. Expatriate allowance in range £280 to £308 per annum. Variable allowance of 35 per cent of basic salary, subject to certain maxima, depending on marital status. Gratuity payable on completion of contract. Housing (if available) at subsidised rental; superannuation. Passages for appointee, wife, and children (maximum five adult passages) on appointment; triennial overseas leave and on termination.

Detailed applications (two copies), naming three referees by September 7, 1967, to Inter-University Council, 33 Bedford Place, London, W.C.1, from whom particulars are available. (520)

#### **CHIEF LABORATORY TECHNICIAN**

Required by the GOVERNMENT OF MALAWI, Ministry of Health, on contract for one tour of 24 to 36 months in the first instance. Commencing salary according to experience in scale £1,980, rising to £2,290 a year. Supplement of £100 a year is also payable. Gratuity (free of Malawi tax) 15 per cent of total salary drawn, rising to 25 per cent for 30 months or more service. Outfit allowance of £30 payable. Government quarters at low rental.

Candidates, over 24 years of age, must be F.I.M.L.T. The successful candidate will be responsible for the overall technical supervision of the various divisions, advising the Pathologist on the methods employed; training and routine administration.

Apply to CROWN AGENTS, M. Dept., 4 Millbank, London S.W.1, for application form and further particulars, stating name, age, brief details of qualifications and experience, and quoting reference M3E/61367/NF. (529)

#### **UNIVERSITY OF MELBOURNE SENIOR LECTURER/LECTURER IN FOREST ECONOMICS AND FOREST MANAGEMENT**

in the Department of Forestry  
Applications are invited for the above-mentioned position.

**QUALIFICATIONS:** Qualifications in economics (including agricultural economics) and forestry are desirable, but qualifications in one with experience in the other would be acceptable.

**DUTIES:** To develop teaching and research in forest economics and related aspects of forest management. The appointee will be required to teach to advanced level and to pursue research and supervise research work and postgraduate studies.

**SALARY:** Lecturer, \$A5,400 to \$A7,300; Senior Lecturer, \$A7,500 to \$8,750. Initial salary will be determined according to qualifications and experience.

Further information, including details of F.S.S.U. type superannuation, travel and removal expenses, housing assistance and conditions of appointment, is available from the Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1. Applications close in Australia and London on September 30, 1967. (554)

## **NEW DRUG RESEARCH**

**Have you had Experience  
or are you interested in any  
of these topics?**

### **SYNTHESIS**

*Amino Acids  
Peptides  
Heterocyclics  
Sulphur Chemistry*

### **ANALYSIS**

*Analysis of Drugs  
Autoanalytical Techniques  
Elemental Analysis  
Chromatographic Techniques*

### **BIOLOGICAL EVALUATION**

*Bioassay Techniques  
Toxicology and Pharmacology of Drugs  
Histology*

**OUR AIMS:** We are interested in synthesising new compounds that might be usefully employed in the control and correction of metabolic disorders.

**OUR NEEDS:** An expansion of our research activities has created several vacancies for *organic chemists and analysts, biologists, physiologists, and pharmacologists*, within the new research laboratories of Horlicks Pharmaceuticals Limited.

**OUR LOCATION:** The laboratories are situated in the delightful countryside of rural Berkshire adjacent to Windsor Great Park. They offer facilities and a working environment that are compatible with creative research work.

**WE WELCOME:** Application for these posts both from graduates with 1-2 years' experience and those recently qualified with a first or second-class Honours. Applicants are invited to write to:

**The Personnel Manager,  
Horlicks Pharmaceuticals Limited,  
Orchard Lea, Winkfield, Windsor,  
Berkshire.  
Telephone Number: Winkfield Row 2963**

(301)

## **DIRECTOR Biomedical Engineering Department**

The Ottawa Civic Hospital as a large and important University affiliated Institution requires a specialist in the field of biomedical engineering to become head of a new department to be established.

The Director will be responsible for a hospital-wide planning and development programme relative to biomedical engineering, including the provision of consulting, advisory and service functions as well as participation in clinical research projects and teaching programmes.

Applications are invited from candidates with an advanced academic standing (M.D. or Ph.D. level) and current knowledge and experience in biomedical engineering.

Attractive salary and fringe benefits commensurate with qualifications and experience.

**The Executive Director,  
Ottawa Civic Hospital,  
1053 Carling Avenue,  
Ottawa 3, Ontario, Canada.**

F.I.E.E., M.I.Prod.E., F.R.A.S.

FACULTY OF ARTS: Post No. 8

The Governors seek to appoint a Lecturer or Assistant Lecturer in Technology/Social Science to teach and to develop a course in Technology on the B.A. Business Studies and on the Fundamentals of Accounting courses. The course in Technology is intended to provide an appreciation of the influence of technological and scientific developments on business activity and of the role of technological constraints in analyses of business decision. The person appointed will have access to assistance from members of both Arts and Technology Faculties. Candidates must be suitably qualified and/or experienced. Salary within the range Assistant Lecturer Grade B, £955 to £1,845; Lecturer, £1,875 to £2,140, plus London Allowance of £70 per annum.

Application forms and further details from the Academic Registrar to whom completed forms should be returned not later than two weeks after the appearance of this advertisement.

D. B. DENNY, M.A.,  
Chief Education Officer.  
(563)UNIVERSITY OF SYDNEY  
LECTURERS IN CHEMISTRY

Applications are invited for the above-mentioned positions. The duties of one appointee will initially be mainly with first-year classes, and of the other mainly with second and higher year classes. Applicants should hold a Ph.D. degree, have had experience in the presentation of general chemistry at the levels mentioned, and be prepared to carry out research. A list of current investigations and of papers published during 1966, from which existing facilities can be inferred, may be obtained from the Registrar of the University or from Professor R. J. W. Le Fevre. Salary for a Lecturer is within the range \$A4,800 to \$A220 to \$A6,340 per annum. Academic salaries are at present under review.

Information concerning superannuation, housing scheme, sabbatical leave etc., and method of application is obtainable from the Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1. Applications close in Australia and London on September 15, 1967. (551)

COMMONWEALTH  
AGRICULTURAL BUREAUX  
COMMONWEALTH MYCOLOGICAL  
INSTITUTE, KEW, SURREY

Vacancies for taxonomic mycologists in the Institute's identification service.

Qualifications: good honours degree with post-graduate experience of the systematics of micro-fungi.

Starting salary according to age, qualifications and experience, in scale £926 to £3,107 with London Weighting of £45 to £65. Superannuation benefits.

Applications by October 15, 1967, to Secretary, Commonwealth Agricultural Bureaux, Farnham House, Farnham Royal, Bucks, England, from whom application forms and full particulars can be obtained. (X394)

THE AGRICULTURAL RESEARCH COUNCIL requires a Scientific Officer/Senior Scientific Officer for a new post at its Weed Research Organization near Oxford. He will lead a small team to study to effect of phytotoxic chemicals on woody plants and their possible use as defoliant and arboricides. The work will include examination of new compounds under glasshouse conditions and the development of promising results by field investigations. A new laboratory and glasshouse will be available. Good honours degree, adaptability and initiative are essential qualifications. Research experience in weed control or related fields and an interest in chemical control of plant growth desirable. The appointment will be for five years with possibility of renewal. An opportunity for training will be given. Scientific Officer Scale, £926 to £1,574; Senior Scientific Officer (£1,744 to £2,155). F.S.S.U.—For further particulars and application form write to Secretary, A.R.C. Weed Research Organization, Begbroke Hill, Kidlington, Oxford. Completed applications must be received within four weeks of the appearance of the advertisement. (526)

RESEARCH  
FELLOW

Applications are invited for a post of Research Fellow at the Central Electricity Research Laboratories, Leatherhead, where important investigations are in progress on the structural aspects of cooling towers. This work arises in part from the investigation of the collapse of three towers at Ferrybridge, which revealed areas where existing knowledge was inadequate, and in part from the development of entirely new forms of cooling tower structures.

Several difficult and novel problems have emerged in this work. Important examples are the significance of structural defects, the dynamic buckling of shells under wind loads and the stability of geodesic shell structures. These problems demand the ability to discern the significant features of complex structural problems, together with a sound knowledge of the mathematical techniques used in structural analysis.

The appointed Fellow will have a choice of subject for his research and will be encouraged to maintain a professional interest in the latest stress analysis techniques. A permanent appointment on the Board's research staff would be considered.

Applicants must have several years' post-graduate experience in a related field and be familiar with computer techniques.

● The salary, which will be fixed for the three-year duration of the Fellowship, will normally be in the range £2,000 – £2,500 p.a. but an award may be made outside that limit in particular circumstances.

Applications stating full relevant details and present salary to N. Berryman, Personnel Officer (Headquarters), Central Electricity Generating Board, Sudbury House, 15 Newgate Street, London, E.C.1, by 24th August, 1967.

CENTRAL ELECTRICITY RESEARCH LABORATORIES

(514)

THE ARTHUR D. LITTLE  
RESEARCH INSTITUTE

wishes to recruit

## Research Chemists

Due to expansion of our activities, a number of vacancies exist within the Physical Chemistry Section for work in the relatively new field of reverse osmosis. The work which is both interesting and challenging should appeal most to those with a background in physical or analytical chemistry and who are sufficiently versatile to tackle a range of problems as they arise. The qualifications for these posts range from O.N.C. to Ph.D.

The laboratories are situated in pleasant surroundings six miles from Edinburgh and are concerned with long range research projects in the fields of Chemistry, Physics and Biochemistry.

Applications should be sent as soon as possible to the Personnel Officer (further details may be obtained by phoning Dr. F. Forbes, MUS 2434 (STD code 031) on a reversed charge basis) Arthur D. Little Research Institute, Inveresk Gate, Musselburgh, Midlothian.

(546)

SCHOOL OF AGRICULTURE  
ABERDEENTHE NORTH OF SCOTLAND COLLEGE OF  
AGRICULTURE AND DEPARTMENT OF  
AGRICULTURE, UNIVERSITY OF  
ABERDEEN

Applications are invited for the College-paid post of

## ADVISORY NUTRITION CHEMIST

Applicants should have a degree in chemistry, biochemistry or agricultural chemistry, preferably at honours level. They should be over 32 years of age and have had appropriate experience in animal nutrition. Salary, Grade II, £2,193 to £2,651. F.S.S.U. Superannuation. Medical Examination required.

Forms of application and further particulars of the post may be obtained from the College Secretary, Crown Mansions, 41½ Union Street, Aberdeen AB9 1UD, with whom applications should be lodged not later than August 31, 1967. (560)

## JOHN INNES INSTITUTE

A temporary **Research Assistant** is required in the Department of Cell Biology to work on plant cell hybridization. The appointment will be for two years at a salary, according to qualifications, in the range £926 to £1,248 per annum with F.S.S.U. Applicants should have a good honours degree in botany with some postgraduate training or research experience.

Applications should be sent to the Secretary, John Innes Institute, Colney Lane, Norwich, NOR 70F, not later than September 30. (512)

WHITTINGTON HOSPITAL  
HIGHGATE HILL, N.19

Basic Grade Science Graduate wanted for research into the oxygen-binding properties of red-blood cells. Applicants should have some basic knowledge and interest in human physiology.

They should write to Dr. T. L. Dormandy for an appointment at the above address. (448)

**CSIRO****AUSTRALIA****RESEARCH SCIENTISTS-  
TEXTILE RESEARCH****DIVISION OF  
TEXTILE INDUSTRY**

The Commonwealth Scientific and Industrial Research Organization invites applications for two appointments to the staff of its Division of Textile Industry at Geelong, Victoria, Australia. Geelong (pop. 100,000) is situated 45 miles south-west of Melbourne.

Both appointees will participate in research and development concerned with new techniques in textile processing.

Applicants should possess a Ph.D. degree in an appropriate field, or have had postgraduate research experience of equivalent standard and duration supported by satisfactory evidence of research ability. A textile background is necessary but this need not be in wool. Some experience in physics or engineering would also be an advantage.

An applicant with outstanding qualifications and attainments may be appointed at a salary in the range of \$A6,892 to \$A7,974 per annum or \$A8,242 to \$A9,490 per annum. The other position will be for a Research Scientist with salary \$A5,250 to \$A6,622 per annum. Promotion within CSIRO to a higher classification is determined by merit. Salary for a woman is \$A428 per annum less than corresponding rates for men.

Initially the appointments would be for a fixed term of three years but could be extended by mutual agreement. Fares paid for the appointee and dependent family. Further particulars supplied on application.

Applications quoting reference number 464/416, and stating full name, place, date and year of birth, nationality, marital status, present employment, details of qualifications and experience, together with the names of not more than four persons acquainted with the applicant's academic and professional standing, should reach:

Chief Scientific Liaison Officer,  
Australian Scientific Liaison Office,  
Africa House, Kingsway,  
London W.C.2.

by August 25, 1967.

(535)

**COURTAULDS****TECHNICAL  
INFORMATION OFFICERS  
MEN or WOMEN**

COURTAULDS has vacancies for Information Officers (men or women) in its Patent and Technical Information Department at Coventry. The work involves abstracting, classifying, and searching the technical and patent literature, principally in the fields of fibre chemistry and production and textile engineering.

Qualifications: a degree or equivalent in chemistry or textile technology. Some experience of information work desirable. Age 20/35.

Candidates should write for a detailed form of application to the Director of Personnel, Courtaulds, Limited, P.O. Box No. 1 AL, 9 Henrietta Place, London, W1, quoting reference number V.16.

(565)

**COURTAULDS GROUP****MONASH UNIVERSITY  
MELBOURNE, AUSTRALIA  
LECTURER IN PHYSICS**

Applications are invited for appointment to this position in the Physics Department. The Department of Physics has active research interests in theoretical and experimental solid state physics, for which a range of facilities is available. Current research projects are concerned with low temperature physics (<sup>3</sup>He and <sup>4</sup>He), superconductivity, magnetism, optical properties of solids, laser physics, solid state plasmas, electron microscopy, E.S.R. and N.M.R. spectroscopy, nuclear orientation, Mössbauer effect. Further information on the Department is obtainable from the Chairman. The salary scale at present is \$A4,800 to \$A6,300 per annum, but is under review and substantial increases are expected effective from July 1, 1967. Superannuation on the F.S.S.U. basis is provided.

Benefits: Travelling expenses for appointee and family; removal allowance; repatriation after three years if desired; subsidised housing initially; STUDY LEAVE is granted at the rate of one term's leave for six terms' service, with provision for financial assistance. Loans for home purchase are available.

General information is available from the Academic Registrar, Monash University, Clayton, Victoria, Australia, or the Secretary-General, Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London S.W.1.

Closing Date: September 29, 1967.

The University reserves the right to make no appointment or to appoint by invitation at any time. (556)

**UNIVERSITY COLLEGE OF  
NORTH WALES  
BANGOR****SCHOOL OF PLANT BIOLOGY  
RECLAMATION OF METAL  
CONTAMINATED SOILS**

Applications are invited for the post of Research Assistant to investigate the use of plant populations tolerant to toxic metals for the reclamation of toxic mine waste. The work will include the investigation of ecological conditions on metalliferous mine workings and the development of genetic reservoirs of adapted material. A full-time laboratory technician will be available, and there will be support for travel outside the British Isles. Applicants should have a good honours degree and interests in plant ecology, genetics, or mineral nutrition. Salary, £775 to £825 for a period of three years, with superannuation.

Further details can be obtained from the Registrar, to whom applications should be sent, together with the names of two referees, before August 31, 1967. (574)

**WHARFEDALE HOSPITAL  
MANAGEMENT COMMITTEE  
WHARFEDALE GENERAL HOSPITAL  
MIDDLETON, NR. ILKLEY, YORKS  
ALLERGY RESEARCH UNIT**

Applications are invited from graduates for the post of IMMUNOLOGIST in the Allergy Research Unit. Candidates should have a degree in a biological science, together with appropriate postgraduate training or practical experience. The successful candidate will be required to undertake work in the immunological aspects of Respiratory Disease.

Further particulars from the Group Secretary, Wharfedale General Hospital, Otley, to whom applications, stating age, qualifications and experience should be sent immediately. Closing date August 19, 1967. (573)

**UNIVERSITY OF IFE  
NIGERIA**

Applications are invited for (a) Senior Lectureships (2) and (b) Lectureship in Department of Physics. Preference given to candidates with qualifications and experience in the following fields: (i) Applied Physics, especially Electronics and related subjects. Candidates with qualifications in Electrical Engineering considered; (ii) Geophysics, Pure and Applied; (iii) Theoretical Subjects, especially Classical and Quantum Mechanics, Mathematical Methods. Salary Scales (a) £2,275 to £2,575 per annum; (b) £1,200 to £2,175 per annum. 20 per cent supplementation basic salaries (generally free of income tax) payable to U.K. staff; Superannuation Scheme; return family passages; children's and car allowances; annual U.K. leave, where applicable.

Detailed applications (six copies), naming three referees by September 4, 1967, to Inter-University Council, 33 Bedford Place, London W.C.1, from whom particulars are obtainable. (523)

# NATURAL ENVIRONMENT RESEARCH COUNCIL

## NATURE CONSERVANCY

### 3 Posts : SCIENTIFIC OFFICER CLASS

#### 1 Post : EXPERIMENTAL OFFICER CLASS

The Natural Environment Research Council has vacancies at the following Nature Conservancy stations.

(1) **ATTINGHAM PARK, SHREWSBURY.** A SENIOR SCIENTIFIC OFFICER/SCIENTIFIC OFFICER AND AN EXPERIMENTAL OFFICER/ASSISTANT EXPERIMENTAL OFFICER to work in the newly established conservation and land use section.

**Duties:** The section, which will operate on a Great Britain basis, will deal with selected projects involving large-scale changes in land and water use.

**Qualifications S.S.O./S.O.:** A good honours degree in a relevant subject, with knowledge of ecology and practical experience in conservation. Preference will be given to candidates with a special knowledge of (a) geography and plant ecology or (b) vertebrate zoology and agriculture of forestry.

**Experimental Officer/A.E.O.:** General Certificate of Education (or equivalent) in five subjects, two of which should be mathematical or scientific subjects at Advanced level. At age 22 entrants are expected to have a pass degree (or equivalent).

(2) **BANGOR HEADQUARTERS.** A SENIOR SCIENTIFIC OFFICER/SCIENTIFIC OFFICER to work in the Pedology Section.

**Duties:** To provide advice on pedological problems relevant to conservation and research. The work includes mineralogy of soils and their parent material, morphology, clarification, distribution, and chemical and physical characteristics in relation to ecological problems with particular reference to upland soils in Wales.

**Qualifications:** A good honours degree in preferably chemistry, geology or soil science with post-graduate experience.

(3) **MONKS WOOD EXPERIMENTAL STATION, HUNTINGDON.** A SCIENTIFIC OFFICER/SENIOR SCIENTIFIC OFFICER to work in the Toxic Chemicals and Wildlife Division.

The person selected will take charge of the laboratory working on pesticide residues using gas-liquid chromatography. He will have an Assistant Experimental Officer and two Scientific Assistants as his staff.

**Qualifications:** a good honours degree in Chemistry, Agricultural Chemistry or Biochemistry with post-graduate experience.

**Salaries:** Senior Scientific Officer Grade (normally at least 26 years and under 32 years at December 31, 1967), £1,744 to £2,155.

Scientific Officer Grade (under 29 years at December 31, 1967), £926 to £1,574.

Experimental Officer Grade (at least 26 and under 31 years at December 31, 1967), £1,365 to £1,743. Assistant Experimental Officer Grade (18 and under 28 years at December 31, 1967), £568 (age 18) to £1,017 (age 26) to £1,243.

Initial appointment will be on unestablished terms, but there are prospects of a permanent and pensionable appointments.

Application forms and further particulars available from The Natural Environment Research Council (E), State House, Holborn, W.C.1.

Closing date: August 29, 1967. (522)

## UNIVERSITY OF CAMBRIDGE CHAIR OF MATHEMATICAL PHYSICS

Applications are invited for the newly established Professorship of Mathematical Physics. Preference will be given to candidates whose work is in the field of Theoretical Quantum Physics. Pensionable stipend £4,360.

Applications (ten copies) marked "Confidential" should be sent by October 21, 1967, to the Registry, The Old Schools, Cambridge, from whom further particulars may be obtained. (569)

# assistant librarian

The Nicholas Research Institute require a librarian to be responsible for the day to day running of its Technical Library.

Applications are invited from either librarians with a scientific background or from young science graduates interested in information work.

The Company has a non-contributory Pension and Life Assurance Scheme and also a Profit-Sharing Plan.

Please write, giving full details to:

D. J. Goddard, Esq., Personnel Manager (R/G/9),

**NICHOLAS RESEARCH INSTITUTE LTD,**  
225 Bath Road, Slough, Bucks.

A MEMBER OF THE ASPRO-NICHOLAS GROUP

(561)

## Leading Swiss Chemical Firm requires

# AGRONOMIST FOR INDONESIA

### Qualifications :

Degree in entomology

Experience with insecticides and in experimental techniques.

### Responsibilities :

Evaluating insecticides in Sumatra.

Supervision of trials of demonstrations in rice.

Promotional activities for insecticides.

Applicants should send their handwritten *curriculum vitae* together with references to

Box No. 931, *Nature*, T. G. Scott & Son Ltd., 1 Clements Inn, London, W.C.2.

Employees of the firm are aware that this position is being advertised.

(X585)

## UNIVERSITY OF WESTERN AUSTRALIA TEMPORARY LECTURER IN CLINICAL PSYCHOLOGY

Applications are invited for the above-mentioned appointment on the staff of the Department of Psychology (Professor A. J. Yates) for a period of one year from September, 1967. The appointee will be required to teach in the course for the M.Psych. Degree and to assist with course administration and organization. The current salary range for the post is \$A4,800 to \$A6,340 but is likely to become \$A5,400 to \$A7,300 per annum in the near future. An allowance will be made towards fares.

Intending applicants are requested to obtain details of the procedure to be followed in applying for the post and a copy of the conditions of appointment before submitting their applications. This information is available from the Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London S.W.1. Applications close in Australia and London on September 10, 1967. (552)

## EWELL COUNTY TECHNICAL COLLEGE DEPARTMENT OF BIOLOGICAL SCIENCES PHARMACOLOGY

Senior Technician (T3) required for September 1. To be in charge of the technical services of this Section of the Department.

### PHYSICS

Technician required for September 1, or as soon as possible thereafter. To maintain and develop electronic and optometric equipment used in all branches of applied biology, and to assist in the preparation of biophysics classes.

The appointment may be made on any of the grades T3, T2 or T1, according to the qualifications and experience of the successful applicant. Salary scales, T3, £820 to £1,020; T2, £735 to £860; T1, £315 to £735. A London weighting allowance of £30, £50 or £75 according to age is payable in addition.

Application forms from the Registrar, Ewell County Technical College, Reigate Road, Ewell, Surrey. (578)

# MEDICAL RESEARCH COUNCIL

## SENIOR ADMINISTRATIVE APPOINTMENT

THE MEDICAL RESEARCH COUNCIL will have a vacancy shortly for a University graduate, preferably aged 35-45, for work in the Administrative Division of their Headquarters Office. The work will be concerned with all administrative aspects of the formulation of Council policy and its execution. The duties fall mainly under the four following heads (1) the administration of the Parliamentary grant-in-aid and the Council's endowment funds (2) the management of the Council's building programme and other arrangements for accommodation for the Council's staff (3) the personnel work arising from the Council's staff of over 3,300 in many different grades at home and abroad, and (4) the administration of the Council's programme of research grants, scholarships and training awards and the control of the budgets for laboratory supplies, equipment and recurrent expenses.

Salary scale—the Civil Service Assistant Secretary scale (starting pay at present £3,500 a year rising to £4,500 by six annual increments, with a London allowance of £85 a year).

The appointment will be a permanent one subject to the satisfactory completion of a trial period, the length of which will depend on age and experience but should not normally exceed one year.

*Superannuation provision: Federated Superannuation System for Universities. Apply, giving full curriculum vitae and names of two professional or business referees, to:*

**Establishment Officer, Medical Research Council,  
20 Park Crescent, London, W.1 by 8th September, 1967.  
(quoting E2/337/N)**

(568)

## INFORMATION SCIENTIST

Expansion of the existing library and information service is taking place at the Ranks Hovis McDougall Research Centre at High Wycombe. This is concurrent with the opening of a new major laboratory unit which will result in greatly enlarged research facilities for the Group.

A young man or woman under 25 with a good degree in chemistry, biochemistry or other discipline relevant to work in the field of food science and technology, is required for the post of Assistant Information Officer.

Previous experience of information work is desirable, but applicants without it will be considered if they can evince a strong inclination for this kind of work and a willingness to provide a really useful service for their colleagues on the bench.

This appointment offers scope and good financial reward. Some help might be given with studying for a further qualification.

*Please write with details of qualifications and career to the Research Manager,*

**RANKS HOVIS McDOUGALL (RESEARCH) LTD.,**

**Cressex Laboratories,  
Lincoln Road, High Wycombe, Bucks.**

(517)

## Immunologist/ Zoologist

A graduate is required for an active research programme in the A.R.C. Cattle Blood Typing Service. One of the important lines of investigation is the study of white cell and tissue antigens in cattle and other species. Excellent laboratory facilities are available. A person with some immunological experience is preferred. It will be possible to study for a Ph.D.

Appointment in the range of S.O. £926 to £1,574 or S.S.O. £1,744 to £2,155 with F.S.S.U. benefits.

Applications to and further details from the Secretary, A.R.C. Animal Breeding Research Organisation, West Mains Road, Edinburgh, 9. (525)

## UNIVERSITY OF DUNDEE

### COMPUTING LABORATORY

A vacancy occurs for a LECTURER or ASSISTANT LECTURER who will be required to give lectures on programming languages and techniques to undergraduate and graduate students and to advise computer users on the preparation of programmes. The Laboratory is installing an Elliott 4130 Computing System which will include magnetic tape, disc files, and remote access consoles. Salary scales: Lecturer, £1,470 to £2,630; Assistant Lecturer, £1,105 to £1,340, with placing according to qualifications and experience. F.S.S.U.; grant towards removal of household effects.

Applications (6 copies), containing the names of three referees, to be lodged by September 2, 1967, with the Secretary, The University, Dundee, from whom further particulars may be obtained. (518)

## BROOKE BOND RESEARCH LABORATORIES

BLOUNTS COURT, SONNING  
COMMON, READING, BERKS

Owing to the expansion of research effort several vacancies will occur in the near future for Graduates in Chemistry, Biochemistry, Botany, or Food Technology.

One of the posts will be for an **Information Scientist**, the remainder being concerned with research and development. It is anticipated that one of the successful candidates will be stationed in Kenya for at least one tour of duty whilst the others will be located in new research laboratories near Reading. The starting salary will be commensurate with age and experience. The Company operates a contributory pension scheme.

Applications (in duplicate, please) to Head of Research at the above address. (544)

## UNIVERSITY OF OXFORD DEPARTMENT OF ZOOLOGY

Principal Technician required September 1967 to be in charge of Chemistry teaching laboratories and to be responsible for supervision of all first-year teaching laboratories in a new building to be ready for occupation in 1969. Salary according to age, qualifications and experience, on University scale.

Applications, with full details and names of two referees to be sent to the Administrator, Department of Zoology, Parks Road, Oxford. (576)

# WOOLWICH POLYTECHNIC LONDON, S.E.18

## DEPARTMENT OF BIOLOGY AND CELL SCIENCE

### SENIOR LECTURER OR LECTURER IN BIOCHEMISTRY

Applications are invited for this post to commence September 1, 1967, or as soon as possible thereafter. In addition to teaching undergraduate and postgraduate students the successful applicant will be required to collaborate with Dr. P. B. Gahan in studies on lipid-protein metabolism or enzyme pathways in ageing, for which full facilities are available.

Salary scales: Senior Lecturer, £2,140 to £2,380 plus £70 London allowance; Lecturer, £1,875 to £2,140 plus £70 London allowance.

Closing date: September 8, 1967.

Assistance may be given towards household removal expenses.

Particulars and application form from Clerk to the Governors, Woolwich Polytechnic, Wellington Street, London, S.E.18. (575)

## PRINCIPAL SCIENTIFIC OFFICER AND SENIOR SCIENTIFIC OFFICER

### EAST AFRICAN COMMON SERVICES ORGANISATION

A Principal Scientific Officer and a Senior Scientific Officer are required at the East African Institute for Medical Research, Mwanza, Tanzania, to plan and carry out research on Schistosomiasis and methods of control and also to train newly appointed science graduates in research methods.

Candidates must be citizens of and permanently resident in the United Kingdom or the Republic of Ireland. They must possess a degree in Zoology preferably "Honours" or a Medical degree, and postgraduate research experience in tropical parasitology. Postgraduate degrees (e.g., Ph.D., M.Sc., etc.) desirable but not essential.

Salary according to qualifications and experience in scale £1,818 to £3,159 per annum for Scientific Officers and in scale £2,448 to £3,000 per annum for medical research officers. Terminal gratuity. Free family passages. Education allowances. Accommodation available at low rental. Two-year contract. Generous paid leave on completion.

Please apply for further particulars and application forms stating full name to:

THE MINISTRY OF OVERSEAS  
DEVELOPMENT,  
Room 403,  
Eland House,  
Stag Place,  
London, S.W.1. (571)

## UNIVERSITY OF LIVERPOOL

### THE HARTLEY BOTANICAL LABORATORIES

Applications are invited for the post of TEMPORARY DEMONSTRATOR/ ASSISTANT LECTURER or LECTURER in BOTANY for the period October 1, 1967 to September 30, 1968. Preference will be given to candidates with an interest in Plant Physiology or Plant Biochemistry. The initial salary will be in the range £895 to £1,285 per annum for a Demonstrator; £1,105 to £1,340 per annum for an Assistant Lecturer; or £1,470 to £1,740 per annum for a Lecturer.

Applications, including the names of three referees, should be submitted by August 26, 1967, to the Registrar, The University of Liverpool, Liverpool 3, from whom further details may be obtained.

Please quote Ref.: RV/120/N. (566)

# analytical chemist

A well-qualified analytical chemist is required, for an expanding programme of analysis for pesticide residues in crops, soil and animal tissues. We are looking for a man aged between 25 and 35 with either a Ph.D. in Chemistry or a good honours degree plus experience in this or a related field. The successful applicant will be expected to provide and apply creative ideas in a well-equipped active department, working in parallel with chemistry, biology and toxicology teams, in a large Research Station, 12 miles south of Cambridge, concentrating on pesticides. An attractive salary is envisaged. *If you are interested please write for an application form (Quoting Ref. No. 122/10) to:*

# FISONS

Personnel Officer,  
Chesterford Park Research Station,  
FISONS PEST CONTROL LTD.,  
Nr. Saffron Walden, Essex. (536)

# PHYSICIST

## UNITED KINGDOM ATOMIC ENERGY AUTHORITY, WANTAGE RESEARCH LABORATORY, BERKSHIRE.

The Wantage Research Laboratory, which is generally concerned with the application of radioactive materials to scientific and technological problems, has a vacancy for a physicist to develop methods of elemental analysis based on the interaction of radiations with matter. X-ray, beta-particle and neutron attenuation and scatter, and X-ray fluorescence techniques now form the basis of instruments for on-line analysis and of portable instruments for use in factory, laboratory and field conditions. There has been a rapid development and extension of instruments of this type during recent years and many new and important applications have been established.

A vacancy exists in the team exploring new techniques for automatic process control and geological prospecting. Current problems include studies of inter-element effects and the effects of grain size in X-ray fluorescence analysis of mineral ores. It should appeal to a physicist with combined theoretical and experimental interest in radiation interactions who wishes to extend his experience to problems of immediate economic importance.

Although previous experience in radiation measurement is desirable, ability, enthusiasm and drive are more important and recent graduates with these qualities are encouraged to apply.

Candidates should have a 1st or good 2nd Class Honours degree. The appointment will probably be made to the grade of Scientific Officer, with a starting salary in the range £995 to £1,685, but an exceptional candidate might be appointed as a Senior Scientific Officer, with a salary range £1,870-£2,310.

Authority housing will be available for married officers living beyond daily travelling distance.

For further details and application forms please write to:

Personnel Department A (A.5198/34),  
Atomic Energy Research Establishment,  
Harwell, Didcot, Berks. (539)

## UNIVERSITY OF NOTTINGHAM DEPARTMENT OF PHYSIOLOGY AND ENVIRONMENTAL STUDIES

Applications are invited for the post of LECTURER in Plant Physiology. Candidates should preferably have a first degree and postgraduate training to Ph.D. level in Plant Physiology, Biochemistry or Biophysics. Salary will be within the range £1,470 to £2,630 per annum.

Forms of application and further particulars, returnable not later than September 1, 1967, from the Registrar. (533)

## THE UNIVERSITY OF MANCHESTER MANCHESTER, 13

### RADIATION OFFICER IN THE

### DEPARTMENT OF PHYSICS

Applications invited from graduates for this post. Knowledge of radiation protection and electronics additional qualifications though not essential. Salary range per annum: either £920 to £1,525; or £1,450 to £2,200, according to qualifications and experience. F.S.S.U.

Particulars and application forms (returnable by August 26), from the Registrar. Quote ref. 120/67/Na. (441)

## BIOCHEMISTRY

### UNIVERSITY OF ALBERTA

### EDMONTON, ALBERTA, CANADA

Applications are invited from potential Post-Doctoral Fellows in Biochemistry for research into physicochemical aspects of lipid-protein interactions. Stipend \$6,000 and over (tax free).

Apply to Dr. P. G. Baron, Department of Biochemistry, University of Alberta, Edmonton, Alberta, Canada, enclosing details of academic attainments and names of two or three referees. (547)

SENIOR TECHNICIAN OR TECHNICIAN required for Microbiology at Queen Mary College (University of London), Mile End Road, E.1. Previous experience is essential and the possession of the I.S.T. or City and Guilds Science Laboratory Technician's Certificate, preferably advanced, or O.N.C. or similar qualification is desirable though not essential. Salary according to age and ability on the scale £912 to £1,150 or £653 to £938 per annum plus London weighting £60 and possible £30 or £80 special qualification award. Five-day week. Four/five weeks annual leave. Pension scheme.—Letters only to Registrar (B/ST), stating full details of age, experience and present work. (558)

## CSIRO AUSTRALIA

### RESEARCH SCIENTIST DIVISION OF PLANT INDUSTRY F. C. PYE FIELD ENVIRONMENT LABORATORY

**GENERAL.** The F.C. Pye Field Environment Laboratory located at Canberra, A.C.T., conducts experimental and theoretical research into the physics of plant environments and plant growth processes. Its facilities include laboratories for studies in soil physics, gas physics, solar radiation, fluid mechanics, micrometeorology, and biology, as well as mobile laboratories for studies of the field environment of plants. It has access to the CSIRO CDC 3600 computer and to CERES, a controlled environment research facility. The laboratory's staff includes mathematicians, physicists and biologists.

**DUTIES.** The appointee will have the opportunity to undertake research in one of the following fields: (a) Mathematical Ecology; (b) Transfer processes within plants; (c) The mechanics of plant growth.

(a) **Mathematical Ecology.** One of the Laboratory's aims is to contribute to quantitative aspects of ecological methodology and theory. The appointee would be expected to develop a research programme in this area. Typical topics could be the mathematical-statistical description of the spatial distribution of plants and foliage, and the dynamics of population growth and dispersal.

(b) **Transfer processes within plants.** The appointee would be expected to conduct research into the mechanisms of movement of water and solutes within the plant, and the effects of water stress on these processes. Some integration of this work with current studies of the transfers of water vapour and carbon dioxide in the field and the water relations of plants would be expected. Liaison with the Division's Plant Physiology Section which is concerned with problems of translocation within the plant would also be encouraged.

(c) **The mechanics of plant growth.** This appointment is for investigations of mechanical aspects of the growth and function of plant tissues. Typical topics could be: mechanical aspects of cell enlargement, particularly in relation to the uptake and movement of water; the propagation of turgor through cells; root penetration and elongation and the uptake of water and nutrients; momentum transfer and the oscillation of foliage elements.

**QUALIFICATIONS.** Applicants should have a Ph.D. degree, or have had appropriate postgraduate research experience of equivalent standard and duration, supported by satisfactory evidence of research ability. For (a), training in Mathematics or Statistics is required, while for (b) and (c) training in Physics, Biophysics or Physiology is required.

**SALARY.** Depending upon qualifications and experience, the appointment will be made within the salary ranges of Research Scientist, \$A5,250–\$A6,622 p.a. or Senior Research Scientist, \$A6,892–\$A7,974 p.a. An applicant with an outstanding record of research achievement would be considered for appointment as Principal Research Scientist, \$A8,242–\$A9,490 p.a. Salary rates for women are \$A428 p.a. less than the corresponding rates for men. Promotion within CSIRO to a higher classification is determined by merit.

**CONDITIONS.** The duration of the appointment will be determined in consultation with the successful candidate; some applicants may prefer a fixed term appointment for three years. Fares paid for the appointee and his dependent family. Further details supplied on application.

Applications, quoting reference number 130/870, and stating full name, place, date and year of birth, nationality, marital status, present employment, details of qualifications and experience, together with the names of not more than four persons acquainted with the applicant's academic and professional standing should reach—

The Chief Scientific Liaison Officer, Australian Scientific Liaison Office, Africa House, Kingsway, London, W.C.2, by the 8th September, 1967. (577)

### UNIVERSITY OF NATAL DEPARTMENT OF GEOLOGY AND GEOGRAPHY

Applications are invited from suitably qualified persons for appointment to the post of LECTURER IN GEOLOGY AND GEOGRAPHY, Pietermaritzburg. The salary scale attached to the post is: R.3,000 by R.150 to R.4,800 (£1,500 by £75 to £2,400) per annum. The commencing salary notch on this scale will be determined by the qualifications and/or experience of the successful applicant.

Further particulars of the post and of the concomitant amenities such as travelling expenses on first appointment; pension, medical aid, staff bursary and housing loan schemes; long leave conditions, etc., are obtainable from the Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1. Applications, on the prescribed form, close in South Africa and London on September 15, 1967. (555)

### UNIVERSITY OF ALBERTA EDMONTON, ALBERTA, CANADA DEPARTMENT OF PHARMACOLOGY

Applications are invited for the post of Assistant Professor or Associate Professor in the Department of Pharmacology from persons interested in Cardiovascular Pharmacology or Biochemical Pharmacology. The salary scale attached to this position is \$9,000 to \$12,450 for an Assistant Professor or \$12,500 to \$16,550 for an Associate Professor. The commencing salary will depend on the qualifications and experience of the successful applicant.

Further particulars of the position and of the concomitant amenities such as travelling expenses on first appointment and pension scheme may be obtained from Professor G. B. Frank, Department of Pharmacology. (513)

### UNIVERSITY OF SHEFFIELD DEPARTMENT OF GEOLOGY

Applications are invited for a post of ASSISTANT LECTURER or LECTURER IN APPLIED GEOLOGY with particular interests in Economic Geology or in fields related to Engineering Geology. The Department is equipped with Geochemical, X-ray Fluorescence and Electron Microscope Laboratories for research in these fields. Initial salary according to qualifications and experience in the range: Assistant Lecturer, £1,105 to £1,340; Lecturer, £1,470 to £2,630, with F.S.S.U. provision.

Further particulars from the Registrar, to whom applications (four copies), should be sent by September 4, 1967. (541)

### MACAULAY INSTITUTE FOR SOIL RESEARCH SPECTROCHEMISTRY

Experimental or Assistant Experimental Officers required to fill three vacancies in the Department of Spectrochemistry, to take part in the general analytical work of the department and in the application of direct reading techniques to soil and plant analysis. Applicants should have interests in physico-chemical or electronic techniques, general analytical chemistry, geochemistry or soil science and should possess an ordinary degree, H.N.C., or equivalent qualification in a relevant scientific subject. Salary on the A.E.O. scale (£744 at age 21 years, £1,017 at age 26 or over, rising to £1,243) or E.O. scale (£1,365 to £1,734) according to age and experience. Contributory superannuation scheme.

Application forms obtainable from the Secretary, The Macaulay Institute for Soil Research, Craigiebuckler, Aberdeen, AB9 2QJ, to whom they should be returned by September 11, 1967. (572)

### SIR JOHN CASS COLLEGE RESEARCH ASSISTANTSHIPS IN PHYSICS

A number of Research Assistantships in Physics will be available from September 1, 1967 for graduates with First- or Second-class (Upper or Lower) Honours degrees to undertake postgraduate research leading to M.Phil. or Ph.D. Internal degrees of the University of London.

The research interests are Magnetic thin films; Surface physics in u.h.v.; Scintillation processes (u.v. and X-ray); Dielectric properties of solids; Flow anisotropy in liquids.

Salary £810 by £30 to £870 per annum (to include six hours weekly demonstrating). Applications to the Head of the Department of Physics, Sir John Cass College, Jewry Street, London, E.C.3. (548)

### UNIVERSITY OF LANCASTER SCIENTIFIC OFFICER

Applications are invited for a post of Scientific Officer in the Department of Chemistry. The person appointed is expected to have postgraduate (or equivalent) experience in one or more of the following techniques—G.L.C., I.R. spectroscopy, N.M.R. spectroscopy, mass spectrometry; he will be responsible for the day-to-day running of instruments and will be required to give assistance to research workers in the department. The starting salary is likely to be about £1,200 per annum, and the appointment will be for three years in the first instance.

Further particulars may be obtained from Professor J. C. Bevington, Department of Chemistry, St. Leonardgate, Lancaster, to whom applications should be sent before September 1, 1967. (542)

### UNIVERSITY OF LEEDS DEPARTMENT OF INORGANIC AND STRUCTURAL CHEMISTRY

Applications are invited for a POST DOCTORAL FELLOWSHIP in THE DEPARTMENT OF INORGANIC AND STRUCTURAL CHEMISTRY at a salary of £1,105 a year. Preference will be given to candidates with some experience in magnetochemistry.

Applications, stating age, qualifications and experience and the names of two referees, should reach Professor H. Irving, Department of Inorganic and Structural Chemistry, The University, Leeds, 2, as soon as possible. (540)

### UNIVERSITY OF SYDNEY CHAIR OF PHYSIOLOGY

Applications are invited for the Chair of Physiology which became vacant on the resignation of Professor P. O. Bishop. Candidates should be qualified in the field of Neurophysiology. Salary will be at the rate of \$A10,400 per annum. Academic salaries are at present under review. There is retirement provision under either the Sydney University Professorial Superannuation Scheme or the New South Wales State Superannuation Scheme. Under the Staff Members' Housing Scheme, in cases approved by the University and its Bankers, married men may be assisted by loans to purchase a house. The Senate reserves the right to fill the Chair by invitation.

A statement of conditions of appointment and information for candidates may be obtained from the Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1. Applications close in Australia and London on September 29, 1967. (553)
